Sanatorium for Treatment of Bone Tuberculosis Not a Nuisance per Se.—Bills were filed by the board of health of a city and by private residents and property holders to prevent the conduct of a sanatorium for tuberculosis. Affidavits filed for the defendant showed that the institution of which complaint was made was not an institution for the treatment of pulmonary tuberculosis, but a sanatorium which was to be devoted exclusively to the treatment of children who are afflicted with bone tuberculosis. The sanatorium was for the free treatment of poor children afflicted with the disease last named, and not being maintained for profit did not come within the provisions of the New Jersey statute requiring a municipal license. The defendant lodged affidavits of a great number of physicians and surgeons of eminence who have given special study to the various forms of tuberculosis. These physicians testified that, while pulmonary tuberculosis is undoubtedly contagious, bone tuberculosis is neither contagious nor infectious, and cannot be transferred from one to another; and that cases of bone tuberculosis are freely admitted to all the hospitals and treated in the same wards as other surgical cases. If that were true it was manifest that no danger to the health of the inhabitants of the city was threatened by the maintenance of the sanatorium in question, and the grievance asserted by the complainants was based upon an assumed danger which did not in fact exist. In view of the evidence of these physicians it was held that the New Jersey act of April 9, 1910 (V. L., p. 279), containing the sentence "Tuberculosis is hereby declared to be an infectious and communicable disease, dangerous to the public health," which was probably not intended to apply to bone tuberculosis, did not render the institution a nuisance *per se* and injunction was denied. Board of Health of Ventnor City v. North American Home, 78 Atl. 677.

Typhoid Fever	119	20
Whooping Cough	42	6
Cerebrospinal Meningitis	3	5
Malarial Fever	—	
Totals	844	201

Rupture of the Uterus During Labor.—Potocki tells us that rupture of the uterus may result from any condition that renders labor difficult, whether it be a contracted pelvis, disease of the soft parts, or a large size of the fetus which renders it out of proportion to the pelvic canal. In case of contracted pelvis it is in the lesser degrees of contraction that rupture of the uterus is likely to result. In great degrees of contraction the condition is foreseen and measures taken to prevent the rupture. In cases of hydrocephalis, or extreme size of the fetus, rupture may occur. Other causes of rupture are cancer of the cervix, or fibromata. An imperfect cicatrix after cesarean section is another cause of rupture of the uterus. If the rupture occurs suddenly we get an intense pain with a sense of tearing, and collapse. If it is less sudden we get pain, bleeding from the uterus, and lesser symptoms. In some cases the rupture is latent and gives few symptoms. The prognosis of rupture of the uterus, unless the rupture is very small, is fatal, death occurring from gangrene, peritonitis, or sepsis. Preventive treatment of rupture consists in the routine examination of every pregnant woman before labor, and provision made against the occurrence of rupture. When rupture has occurred operation should be done at once. Laparotomy becomes necessary to extract the fetus, and this must generally be followed by amputation of the uterus when the cervix is not involved, or hysterectomy when it is.—*Le Bulletin Médical.*

Narcolepsy in Glandular Affections.—Tramonti says that the term narcolepsy signified originally a neurosis in which the principal symptom was an irresistible desire to sleep, occurring in attacks at intervals, accompanying various diseases, especially those connected with various glands. The author considers first narcolepsy in connection with glandular insufficiency. The condition occurs in affections of the liver, such as cirrhosis. In renal diseases it is rarer than in liver disease. It indicates a condition of marked insufficiency of the kidneys, as in acute Bright's disease. It is a common effect of absence of thyroid action and occurs in myxedema occasionally, but more frequently in hypothroidism, in adipose subjects. Here the crises of sleep come on without premonitory symptoms, and are very profound, the patient going to sleep suddenly in the middle of a medical examination. Examination of the thyroid gives no useful information about this condition. Under hyperfunction of glands the author classes the cases of narcolepsy in fat persons who eat a great deal, live a sedentary life, and have dyspepsia. The attacks do not come on suddenly, but slowly, in spite of the resistance of the patient. The hypophysis has a marked influence on the cortical system. Narcolepsy occurs in acromegaly, coming on suddenly in the midst of the occupations of the patient; sleep is complete, profound, and the patient wakes up spontaneously. It also occurs in disseminated sclerosis. The treatment of this condition is unimportant; at the time of the attack it consists in placing him in a comfortable position with loosened clothes. The causes must be found and removed to get permanent results. A severe diet and régime are needed in the obstinate cases found in hepatic and renal conditions. Those attacks that are most benefited by treatment are found in the obese and those suffering from hypothroidism. An anti-fat treatment is of value here. Thyroid opotherapy is also useful.—*Il Policlinico.*

TETANY AND THE SPASMOPHILE TENDENCY IN INFANCY AND CHILDHOOD.*

BY HENRY KOPLIK, M.D.,
NEW YORK.

FOR decades past interest has centered about the study of certain infants and children who in the course of their growth show a tendency to convulsions. The interest has, as it were, been a storm center of investigation and discussion. Why it is that certain infants should show a recurrent outbreak of convulsion under inciting influences which leave others unharmed has as yet not been entirely solved. The term spasmophile has been coined to fit children who have a tendency to show under special conditions spasms of various kinds. This term has been given to us by Heubner and maintained by his school. It has been rejected by Escherich and his pupils in favor of a nomenclature which might more completely unify the pathogeny of the convulsive condition of infancy and childhood. This nomenclature will be discussed more in detail. We may divide all children into (1) those who have never had any convulsions, spasms, or spasmodic affections. Under this head I would class not only those who have not had any convulsive seizures, but those who are not likely to have any under the most trying inciting causes. There are such children.

On the other hand, there is (2) a large class of infants and children who, though they have never had convulsions or even spasmodic affections, may at any moment exhibit them if the inciting agent becomes apparent. Such infants and children show certain characteristics which mark them to the careful observer. They are the so-called tetanoid infants of Escherich or the spasmophiles of Heubner and his school. To one who has seen these infants the striking point is the frequency of their existence if certain tests, of which we shall speak, are applied to them. In Escherich's clinic von Pirquet found fully 56 per cent. of all children, and infants especially, came under this class. In speaking of this class of infants and children, my own feeling has been, as I passed them in review, that of the European observers—their startling frequency. In any large clinical collection of infants or children we see many who come from neurotic parents. As the infant is placed on the examining table the look of anxiety in the face of the mother is reflected in the features of the as yet subconscious mite of humanity. The babe of three months will start and cry as soon as approached from an unknown quarter. Any sudden sound or harsh handling will cause it to jump and then cry. These infants show marked response to the slightest irritation, mechanical or otherwise. They are pale, sometimes quite well nourished, but as the Germans have well put it, "pasteuse," pasty. The signs of beginning rachitis or craniotabes are present, and in older children there is a distinct lymphatic tendency, but what is especially worthy of note is the extreme hypertension of the nervous organization of these young infants and the corresponding characteristics in the parents. The physician is interested, but at the same time realizes that he is in the face of serious conditions. Many, I should say the larger number, of these infants, are artificially fed, though not necessarily so. These infants whom we will for the sake of simplicity call spasmophilic may never have had any convulsions, or spasms, or spasmodic conditions, but their nervous system is ready to accept the first incitement to convulsive affections. We may with moderate certainty predict, if it were advisable, that such an infant will at some future time exhibit convulsions or the convulsive affections of childhood. The infant is in a constant state of tension as to its nervous system or other functions. The least variation in the food or change in the daily routine of such an infant becomes immediately apparent by a series of symptoms all reflected in a constant uneasiness which is not and never would be brought out in children who have not these tendencies. Under the careful guidance of the all-searching mother such an infant may be carried along through a part of its infant life without any mishap, when suddenly an explosion or catastrophe occurs, and the first symptom appears which immediately places the child in a second category, the outspoken tetanoid or spasmophile infants.

The first and by far the most frequent symptom to appear is one of the forms of laryngospasm, and with it one of the variations of respiratory apnea. In the old nomenclature of diseases of infancy laryngospasm, or laryngismus, is described as a distinct affection, the so-called laryngismus stridulus. We know now that this symptom is only a spasmodic manifestation of a deep-seated condition. It is only an outward sign of what may at any moment occur, and that is a convulsion. Going still deeper, laryngospasm combined with apnea may result in sudden death of the individual, a death which is due, not as formerly supposed, to asphyxia from closure of the glottis, for it may occur with wide open glottis, but to spasm of the diaphragm and stoppage of cardiac action, the so-called "*Herztod*" of the Germans.

As I have shown, the first disquieting symptoms are the attacks of laryngospasm and apnea. The mother fears the apnea, and to such a degree that this fear drives her to the physician. When these symptoms have appeared the next development in the clinical journey of these children is the convulsions. The least exciting moment will cause eclampsia, either a frank convulsive seizure or, what is generally the case, a convulsion, following some

*Read before the Harlem Medical Association, May, 1911.

excitement or an attack of laryngospasm or apnea.

A study of these convulsions will mark them as peculiarly characteristic. The infants pass into the convulsions with tetanoid rapidity, there is a suspenion of respiratory movement and a slowing down of the heart. In some cases the suspension of respiration is prolonged until cyanosis is followed by pallor. In such cases death is dangerously imminent, when suddenly there is a resumption of respiration in a shallow manner as distinguished from the sudden deep inspiratory resumption in other cases. Any mild or severe febrile movement will in these infants be ushered in by a frank eclamptic seizure and these seizures may be repeated and prolonged.

These eclamptic seizures or convulsions in the tetanoid infant may be separated by intervals of days or weeks, but usually become more and more frequent until the infant may have repeated convulsions in twenty-four hours, as many as twenty-four in an equal number of hours. These convulsions, frequent as they are, do not seem to injure the sensorium of the infant. Untreated, the infant comes out of the convulsion apparently unharmed. There are no meningeal symptoms or paralyses remaining to mark the path of the convulsive seizure. The most striking element in the convulsion is its startling suddenness and the subsequent freedom from symptoms. The next stage is the appearance of muscular spasm in the intervals of convulsions or laryngismus. A child who at first had laryngospasm or apnea and even convulsions without any interval symptom, will then develop a constant or intermitting spasm of the fingers, arms, and toes, the extremities assume a spastic position and the face wears an anxious look. The so-called carpopedal spasm, or tetany proper, develops in its full symptomatology. This spasm may be evanescent, lasting only a short time, or may be constant and in rare cases last through weeks or months. During the continuance of the tetanoid spasm the infant may have not only recurrent convulsions but repeated attacks of laryngismus. The infants may recover from their tetany or carpopedal spasm, but during convalescence they show the repeated laryngismus and may even have apneic attacks. Others are not so fortunate, but may, in a convulsion or apneic attack, suddenly die as a result of either heart paralysis or paralysis or tetanoid spasm of the diaphragm. In the attack of tetany, unlike the stage of convulsive attacks without tetany, the sensorium may be affected. The face has an ever anxious expression in the stage of carpopedal spasm. This expression may give way to an expression at the height of the tetany of a vacant idiocy; the eyes have a fixed, vacant stare, "*Augenstarre*" of the Germans, and it may be a difficult matter to decide (as in one of my cases) whether the eyesight has not been compromised. Even here, from a vacant, meaningless expression, there may be a return to the normal, and a child who for days has baffled all attempts to fix the presence or absence of blindness will begin to see, and the face will again assume an expression of intelligence and repose.

I have thus sketched the transition of these infants from a series of very insignificant symptoms to the full development of a disease which may at any time threaten life—the full developed "tetany." The general practitioner who for the first time is called to see a spasmophile or tetanoid infant rarely goes deeper than the mere surface, and the result is that he seldom hears of the repeated convulsions of laryngospasm, and the case passes from hand to hand. A close study of the first era in the clinical history of a spasmophilic or tetanoid infant would, I feel, do much to ward off recurring attacks or the full development of tetany. Tetany is not an entity in that it stands alone, but it is the full development of a condition which may be detected in its incipiency and arrested in its onward progress. During the last few years I have given this matter close study and consideration, and have made every effort to recognize the spasmophile or tetanoid infant as it came under my care, and to try to warn those in whose care it was of impending danger.

I have brought together some eighty-two infants and children, of whom twenty-six suffered from fully developed or frank tetany, and the remainder were either spasmophiles or, as we might call them, tetanoid, and would come under the rubric of latent tetany of Escherich and his school. Taking up the discussion of the spasmophile or tetanoid infant, the first question that is of great interest is the bearing of the feeding on the occurrence of this peculiar tendency in infants and children. Of some sixty cases of spasmophilic infants fully thirty-six were fully or in part artificially or substitute-fed infants. It would seem that the simple fact, therefore, of breast or substitute-feeding was not so important as the efficiency of either mode of feeding. Breast milk may be as inefficient a food as cow's milk, and it is in this light that we must consider the feeding as an etiological factor. Therefore, those who insist on breast feeding as the first requisite in the formation of a healthy organism must consider also the full efficiency of this or any mode of feeding. A vast number of artificially fed infants are far from being spasmophiles, and an equal number of breast-fed infants may eventually be tetanoid. Of greater importance, it seems to me, is the presence in overwhelming prominence of the symptoms of rachitis and craniotabes in the spasmophile. Not that rachitis can be proven to be an etiological factor, as Kassowitz would have us believe, but that it is certainly a leading expression of disturbances of metabolism, which in a like manner have caused the appearance of the symptoms which I have sketched, must undoubtedly be admitted. Moreover, I would like to call attention to a factor which is of undoubted bearing in these conditions, and that is the so-called familiar aspect of the problem. I have seen certain families in which generations of children are spasmophiles. I have now under observation a family in which the first born was a manifest spasmophile or tetanoid infant, and in two succeeding members (infants) the spasmophile tendencies are becoming evident, even at the age of three months. In this family the father is rather phlegmatic, while the mother is palpably of high-strung nervous temperament.

The concurrence of the spasmophile or tetanoid tendency with other conditions perhaps closely allied to it, or in some way suggestive of it, is quite interesting. Thus, some seven of my spasmophiles were infants who at the same time showed congenital laryngeal stridor. By this I do not wish to trace any connection between the two conditions, but it would certainly tend to bear out the neurotic origin which some attribute at least to a percentage of the cases of laryngeal stridor. Pyloric spasm, or stenosis, is another affection strongly suggesting a neurosis in certain of its manifestations, and it may be found in a spasmophile.

Little's disease and various forms of idiocy, such as Mongolian idiocy and amaurotic, as well as hydrocephalic idiocy, may show in their symptomatology a distinct tetanoid tendency. I have met the tetanoid tendency in high-strung neurasthenic and hysterical children. To all these I would place the spasmophile or tetanoid tendency in rather a secondary relationship. Spasmus nutans is a distinctly neurotic affection which I have found to be present in spasmophiles. One of my spasmophiles two and one-half years of age showed the symptoms of masturbation. I have intimated that in a large number of the cases spasmophile or tetanoid infants can be immediately recognized by certain familiar traits. At the same time I have found infants perfectly normal early in infancy who later on would manifest tetanoid tendencies which were distinctly absent at first. Infants may show these tendencies very early, even as newborn, but what has struck me as important is that they may be absent at intervals during the first year of life and crop out later on. I have such a case of a breast-fed infant who during his infancy had several periods of freedom from tetanoid symptoms, but during several illnesses ran high temperatures without convulsions. Later on, however, when he had apparently been permanently freed from the attacks of apnea they recurred with renewed and increased severity at the age of twenty-one months. In this case they first appeared at the age of nine weeks.

I now pass to a consideration of the full de-

MANIFEST TETANY.

velopment of the symptomatology of the tetanoid tendency, and that is tetany. Tetany may occur without any previous symptoms having been observed in the infant, or it may appear, as I have said, as a capping stone to the whole symptom-complex of the spasmophile. As a rule infants and children who exhibit the symptoms of frank tetany have shown some spasmophile tendencies during infancy in the form of extreme restlessness, irritability, and attacks of apnea or laryngismus. The symptomatology of tetany is so familiar that to detail it here would be out of place. I will pass in review only those phases of the disease which have left a more lasting impression on my mind. In some cases the first symptoms to appear suddenly, as lightning out of a clear sky, are the convulsions. A breast or bottle-fed infant having been in previous absolute health will suddenly and without any fever or premonitory symptoms develop convulsions. These convulsions may be repeated a number of times during the twenty-four hours, and only after a while do the extremities assume the characteristic tetany position. Laryngismus may be absent, but what is most interesting is that expiratory or inspiratory apnea may usher in the convulsion. The result is that the parents only by close questioning can detect any premonitory stage. The well-being of the infant does not seem to suffer. From this to the most outspoken forms of tetany is only a matter of gradation. Among my cases, of twenty-five in which systematic records were kept fifteen were bottle-fed or partly breast and bottle, the remaining ten cases were breast-fed. Here there is an overwhelming proportion of bottle-fed infants, but at the same time the breast-fed infants were certainly in remarkable proportion, proving again that the efficiency of the breast feeding might well be questioned in these infants. Of my twenty-five cases the most frequent occurrence was from the sixth to the twelfth month, sixteen cases; below the sixth, seven cases, and above the twelfth, two cases.

Of the twenty-five cases only one could be classed as subacute or chronic. In six of the cases the tetany appeared as a so-called accidental affection in the course of pneumonia, meningitis, or gastro-enteric infection. Of the series of twenty-five cases eighteen showed signs of rachitis to a degree, thus showing the overwhelming proportion of cases which have disturbance of bone nutrition.

In three of my cases of frank tetany sudden death occurred, and in another case which complicated tuberculous meningitis death followed, as was to be expected. This latter case showed in a most exquisite manner all the various symptoms of the disease, but in an exaggerated manner, no doubt intensified by the presence of the leading affection.

The diagnosis of tetany is one of the great strides in diagnosis made in modern pediatrics, and is due largely to the increasing activity of the German pediatric schools. I say without fear of criticism that to-day the recognition of tetany in America has not received that full attention which other diseases of infancy and childhood have. It is difficult to account for this. These cases are just as common here as abroad. We have practically the same class of infants and children, but the practitioner and those who devote some time to the study of diseases of children have not given the subject the close, intimate study it deserves. One of the greatest advances in the recognition of the infants I describe is the elaboration of the reactions of these infants to electrical, galvanic, and mechanical stimuli. Erb, Thiemisch, and, more especially, von Pirquet have emphasized the close relationship and sequence of cases of tetany with their development into tetanoid or spasmophile infants. In the so-called spasmophile we have not only a reaction or muscular response to cathodal and anodal stimuli of very slight degree, but in spasmophilic infants the noteworthy fact is that the opening of the anode is followed by prompt muscular reaction

34 CASES OF EPILEPSY.

Number	Age	Time of First Convulsions	Intervals	Number of Convulsions	Loss of Consciousness	Petit Mal	Grand Mal	Remark
1	12 years	4½ years	Weeks	Multiple	+	–	–	Cortical epilepsy in cerebral palsy, hemiplegia.
2	8 years	7 years	2 or 3 mos.	1	+	..	+	Occur also during sleep

34	11 years	....	3 months	Single	+	..	+	

Synopsis: 34 cases of which 21 were manifest epilepsy, one to unknown causes, 16 grand mal, 5 petit mal.
Of these the most frequent period of occurrence was the 6th to 10th year of life. In only one case of manifest petit mal was there cathodal opening below 5 milliamperes.
In 3 cases there was a history of convulsions in early infancy. In one of these, a grand mal, there was anodal open and closure at 3 M A. Cathodal opening and closure 4 in A.
Cases of Epilepsy, 34. 21 manifest uncomplicated, 13 complicated by presence of cerebral lesions.

which is even more marked than the anodal closure. This occurs in response to currents of weak intensity which in normal children are without effect. This has been called by von Pirquet anodal susceptibility and, as with cathodal response, he feels, as I do, that opening anodal response is a distinct earmark of the tetanoid disposition. If in addition there is a cathodal opening contraction to less than five milliamperes we can be moderately certain that the infant belongs to the tetanoid class. In cases of frank tetany so delicate is this test that anodal and cathodal closure, especially opening response, is obtained under currents of such weak intensity as one milliampere. In order to obtain these reactions a reliable milliamperemeter is necessary.

The Chvostek phenomenon, though interesting and characteristic, may be obtained in spasmophiles, but my histories show that at times in frank tetany the reaction may be absent. I do not think the Trousseau phenomenon so valuable. First, it is obtained only in skilled hands, and in rough manipulation it is painful to the infant, and I have as a rule disregarded it, and only shown it to others on occasion. The tetany position of the hand, fingers, and toes, the expression of the face must all have been seen, I find, to be readily recognized. It is quite a common thing to find that in the hospital the house staff will not recognize the very interesting condition of carpopedal spasm unless it is first demonstrated to them. The carpopedal spasm may be absent in a frank case at the outset, but is quick to appear either after repeated convulsions or laryngospasm. The most common mistake is for the physician to diagnose either an impending infectious disease or a meningitis. This is more apt to happen in the cases of secondary tetany, though it may occur in so-called accidental cases of Escherich. I have seen three cases of this kind. In one the infant had had a bronchopneumonia and after two weeks passed into a tetany with convulsions and carpopedal spasm with the mental state of irritability *"Augenstarre,"* that is, mental apathy and pseudo-blindness. This was an infant, rachitic, eleven months of age, with extremely neurotic parentage. When I saw the patient in conference the convulsions and tetany had lasted three weeks, and the apathy and eye symptoms were present with carpopedal spasm of mild degree. The diagnosis of tuberculous meningitis had been made with the result imaginable. The infant recovered completely; it was in convalescence still susceptible to anodal and cathodal irritation both on closure and opening below four milliamperes.

The second case was that of a spasmophile two and one-half years of age, who at the lysis of temperature in a bronchopneumonia went into a condition of spasm of the upper and lower extremities with rigidity of the body, apathy, and apparently blindness and aphasia. This patient recovered, though I would not call this anything but tetanoid, and so diagnosed the case to the physician who made the fatal diagnosis of pneumococcic meningitis. The child had a double otitis, and as soon as this was relieved the peculiar mental state and tetanoid spasm were gradually relieved. The mother in this case was of an extremely nervous temperament.

The third case, which was diagnosed as tuberculous meningitis, was seen by me in my office

and observed for three months subsequently. In this case the tetany poison not only reduced the infant to a state of mental desuetude, but it was for weeks impossible to decide whether the child could see. This child is now mentally normal, and the eyesight is normal. An oculist examined this patient repeatedly and could come to no definite conclusion. The pupils were dilated and the fundus absolutely normal, so that the cause of the loss of sight must be a matter for future study. It may have been due to lack of power to accommodate. The diagnosis of tuberculous meningitis was made in a fourth case, which developed convulsions at the third month on weaning from the breast and changing the food.

The differentiation of these cases of convulsions in spasmophile infants from epileptiform convulsions or epilepsy has been one of the greatest advances in the modern conception of both conditions. The spasmophile or tetanoid convulsion has little or nothing in common with the epileptiform convulsion. The theories of Henoch and teaching of Marie and Sachs that the children who are convulsive, or have had convulsions, are apt to show the symptoms of epilepsy have given way to a more definite conception of epilepsy in children and the spasmophile infant. These children can develop into normal individuals, no matter how much they have suffered from convulsions in infancy and childhood (Thiemisch, Heubner, Birk, Finkelstein, Escherich). In fact, many of them have been studied and followed, and epilepsy has never developed. I have seen these children devlop into normal individuals. Thiemisch and Birk have investigated sixty children who in infancy suffered from convulsions and at the tenth year of life were not epileptic, this in face of the fact that epilepsy is frequent at the sixth to seventh year in its onset is significant.

In a series of thirty-four cases of epilepsy of my case books twenty-one were uncomplicated idiopathic epilepsy and thirteen were the outcome of lesions of the central nervous system, congenital or acquired. The twenty-one cases of idiopathic epilepsy divide themselves into seventeen of grand mal and four of petit mal. The most frequent period of occurrence was from the sixth to the tenth year of life. In only one case of petit mal was there a cathodal opening contracture to a galvanic stimulus below five milliamperes. In three cases only was there a history of convulsions in early infancy. In one of these there was an anodal opening and closure contracture to three milliamperes. This simply demonstrates that whereas a spasmophile may develope epilepsy it does not necessarily follow and epilepsy and spasmophilia are only accidental combinations.

Of great aid in differentiation is the systematic study of cases. The tetanoid or spasmophile infant shows, as I have pointed out, certain definite symptoms and reactions. There are the apnea, laryngospasm, the tetany, facial phenomenon, Trousseau sign, and the disturbance of nutrition. The tests to electrical excitation are above all characteristic, and are found only with rare exceptions, in epileptics. I have seen neurotic older children with marked anodal and cathodal excitability with currents of less strength than five milliamperes, but this is exceedingly rare, and can be disregarded. The convulsions of spasmophiles as a rule occur in rapid succession, are multiple, and are combined with the other signs of spasmophilia. The epileptic convulsion is of varied interval, and may recur after years. The infantile convulsion is excited by some agent, temperature, intoxication. The spasmophile as a rule has a clear family history, and is mentally overbright, the epileptic just the contrary. Fully 30 per cent. of the children in Birk's statistics of epileptics had a family history of epilepsy, and 50 per cent. were weak minded or slow. Another point of overwhelming influence is that convulsions in spasmophiles with tetany occur at certain seasons of the year, in the fall and early spring months. I cannot agree with Thiemisch and Birk that most of the spasmophilics are artificially fed, for I have shown that quite a goodly proportion are breast-fed, and have laid stress on the fact that a breast may be inefficient and lead to nutritional disturbances.

The nature of tetany and its etiology and pathology have been matters of study and speculation. It is a subject which has occupied much attention for decades. The first grouping of symptoms was made by Cheadle, who thought tetany, laryngospasm, and convulsions were different expressions of the same morbid state, associated with rachitis and the period of the first dentition. Preceding this we have the theory of Kopp, then of Hugh Leigh, that laryngospasm was caused by pressure of an enlarged thymus or lymphnode on the vagus. Later on the sudden deaths occurring in laryngospasm were theoretically traced to a disturbance of the function of the thymus gland. As to the more specific cause of tetany and its origin the theories to-day are widely divergent. In the main there are two contending camps, the one that of the Heubner school and his pupils, who have taken up the contention held for a long time that tetany was due to an influence of a poison, a so-called tetany poison, which was thrown into the circulation in artificially fed infants by disturbances brought about by the ingestion of cow's milk, that this poison existed especially in the whey of cow's milk (Finkelstein). This is a rather vague way of placing an old theory. Stölzner, on the other hand, arguing from the constant appearance of tetany in connection with rachitis, has contended that tetany is really a species of poisoning of the central nervous system by calcium salts. The most attractive theory as to the real causes underlying the manifestation of tetany is that of Escherich and Yanase. We may say at the start that it is the only explanation of the phenomena of tetany that seems to be founded on experimental data. Seeing the close similarity of infantile manifest tetany with that which is seen after operations on the thyroid gland, Escherich has ventured the opinion that they are both identical. They are both dependent on some lesion of the parathyroid glands or epithelial bodies which in some way compromises the efficiency of these glands in counteracting, as they do normally, the toxins in the circulation acting on the nervous system. The result is that the toxins act unrestrained, and produce the manifestations of tetany, a so-called parathyreopriva. As a corollary to this is the theory that the calcium salts in some way may be responsible for the immediate exhibition of tetany. Escherich tried through his school to prove that the irregular distribution of calcium salts resulted in the production of tetany and that this distribution was disturbed by an interference with the function of the parathyroid bodies. How this may be brought about Escherich, through Erdheim and Yanase, showed that in cases of manifest

tetany lesions, such as hemorrhagic cysts and parenchymatous changes, were found in the parathyroids in cases of tetany with sudden death. The launching of this theory has been the stimulus to a large amount of investigation of the parathyroid glandules in infancy. One of the contentions of Escherich that hemorrhage in the gland may occur as the result of the great strain on the infant during birth has been taken up by Grosser, Betke, and Auerbach, who have stated that hemorrhages in the parathyroids have been found in a number of conditions, infectious and toxic, in which tetany was absent, and in cases in which the electrical reactions during life were normal. In a recent case of tetany of my own, in which the parathyroids were carefully examined by Oppenheim, the only changes found in the glandules were peculiar dilations of the lymph spaces. The whole matter of the influence of lesions of the parathyroids in causing tetany still remains to be closely studied. Certain it is that of all the hypotheses of the disease thus far broached it is not only the most attractive but one which harmonizes most with our knowledge of tetany elsewhere than in infants.

30 East Sixty-second Street.

THE CONSERVATION OF SIGHT.*

By J. W. JERVEY, M.D.,

GREENVILLE, S. C.

Dearly Beloved Brethren: Let us take for the text of our discourse this morning the eighteenth verse of the twenty-ninth chapter of the Book of Proverbs—"Where there is no vision, the people perish."

Admitting that the words "proverb" and "parable" are in a measure synonymous, it may be that the theologian and commentator will venture the interpretation of the passage in its anagogical sense. Yet we must be pardoned for insisting that the words of the sage of Israel, whatever may have been his identity, can suffer no impairment of their forcefulness through a profane and literal acceptance of their meaning. Hence we mean, at this time, exactly what we say, without parabole or adumbration—"Where there is no vision, the people perish."

Precisely as the race that is stricken blind must perish, so in proportion will that people suffer which is more or less affected of its eyes in a pathological sense. In other words, both a race half of whose people are blind and a race all of whose people are half blind would be seriously handicapped in the struggle for existence—the eternal drama whose finale will be played only when the last surviving thing on earth has perished. Yet, strange as it may seem, with the full knowledge of this trite and axiomatic fact before us, we are daily doing many of those things which we ought not to do, and leaving undone many of the things which we ought to do, if we would preserve for ourselves and our children the eyesight which is our most precious physical heritage. In the beginning was the mandate "Let there be light," "and there was light." But there could have been no light were there no sight to perceive it, any more than there is sound in the primeval forest when the resistless whirlwind fells to the ground the giant oak unless there were some ear to hear it.

*Read before the Tri-State Medical Association of the Carolinas and Virginia, at Raleigh, N. C., February 21-22, 1911.

One of the greatest of modern philosophers has said that consciousness is the first great wonder of the world and next to it comes sight. What is our civilization doing to preserve its eyesight? And, still more to the point, what is the same civilization doing to cripple it? It is with the last question that we shall here concern ourselves. Much is said nowadays about conservation—of lands, of forests, of minerals, of water powers, natural resources the heritage of a nation. Let us who know discuss the conservation of a birthright greater by far than any of these—the priceless property of vision.

It were almost superfluous to point out to a scientific body such as this that a people's vision is the *vade mecum* of its mental and moral balance. From the mere mechanical necessity for the trained and perfect eye, sighting with deadly certainty the guns that bear upon the enemy, to that elaboration and blending of ocular and mental vision by which alone the masters of statecraft can command a true perspective of affairs and men and lead a race to its most lofty destinies, these blessed eyes of ours fulfill a glorious mission.

Many of you know and realize what defective vision means to the individual. Does it mean less to the state and to the nation? Shall we stand idly by and silently permit our fellowmen to offer up in ignorance their daily pitiable sacrifices to the yawning Moloch of ametropia? Are the institutions for the blind to be forever insatiate? Do we not know that our jails, reformatories, hospitals, and asylums are harboring tens of thousands of unfortunates whose moral, physical, and mental unbalance is directly traceable to defective vision, unrecognized and neglected? Can there be any doubt that the tide of world politics has more than once been turned by the peevishness of the ametropic statesman and the ill-considered logic of the restless asthenope?

Then with these pregnant thoughts upon us I shall enumerate here, with very brief remarks upon each count, the principal sins, as I see them, which are daily being committed by a modern, civilized people upon a nation's eyesight. They are all preventable and many of them easily so. And if, as I truly believe, preventive medicine is the medicine of the future, here is a field which will magnificently repay its entry.

I. *Ophthalmia Neonatorum.*—Thirty per cent. of the preventable blindness of the whole world is due to this one cause. And as if that were not pity enough, a greater pity still is that the medical profession as an average whole must share part of the shameful responsibility. In spite of the well-known danger of inflamed eyes in newborn infants; in spite of the universally recognized efficiency of Crédé's method of prevention; and in spite of a social state which spells suspicion in the palace almost as boldly as in the hovel, there are many physicians (not you or I, but others that you and I know) who seldom make a careful personal inspection of the baby's eyes, and still more seldom apply the magic touch of the silver specific. Yet the dawn has broken. The American Medical Association has made, and is now making, a nation-wide effort for the suppression of this blight, and in some States, our own among them, a law has been enacted requiring the parents and attendants upon any birth, on pain of punishment, to report and provide for the proper care of any inflammation, however mild, appearing in the eyes of the infant. Still, it remains for us, no doubt, to insist upon the enforcement of the statute.

II. *The Pernicious Activity of the So-Called "Optometrists."* One of the most active cults of recent years is that of the optometrists, which is but another name for opticians. They claim ability to differentiate pathological conditions of the eye structures, and loudly voice their superior qualifications for doing refraction work. By shrewd and insistent efforts these bands of charlatans with a central national organization have succeeded in many States in having their trade regulated by statute, with "state boards of optometry examiners," thus lending the apparent sanction and official recognition of the government to their preposterous claims. They are, of course, commercialists in the very vulgarest sense of the term and their whole aim and object is to ensnare victims and never let them loose until wonderful glasses are sold at still more wonderful prices. These vampires, most of whom are without even a high-school education, and all of whom impudently and falsely assume a knowledge which they do not possess, are daily all over this great country committing a grossly commercial rape upon the eyesight of the nation! Many physicians have been misled by specious arguments into sanctioning the practice of the optometrists. The recognition of the latter by statute is a direct blow at the public health, because it is letting down the bars of medical practice requirements, by which alone the health of the people can be safeguarded. If the care of the eye in any of its abnormal phases is not a part of the practice of medicine, then neither is the care of the lungs or the stomach, or the heart, or any other organ, and we should soon expect to see separate and distinct state boards of examiners for each group of imposters who would spring up, like mushrooms in the night, claiming superior skill in some particular specialty. Can anything short of a competent medical education enable any man to differentiate and diagnose, as their symptoms appear in the eye, such conditions as albuminuria, diabetes, arteriosclerosis, brain tumor, accessory sinus disease, the toxic amblyopias, syphilis, tubercle, etc., to say nothing of the dangerous localized intraocular diseases? Would not and does not the "optometrist" try to sell a pair of glasses to every such victim that he can lay his hands upon? Assuredly he does, and every oculist of even moderate practice is constantly confronted with the damage, much of it irreparable, which these conscienceless fakers have wrought. And the optometrist can do refractive work no more safely than he can diagnose disease. Competent refraction, in the vast majority of instances, requires the use of a mydriatic. The optician cannot use drugs, not being a licensed physician, therefore he can not employ the mydriatic. There can be but one result. Thousands upon thousands of innocent victims, victims of specious advertising and swindling imposture, are to-day unwittingly injuring their minds and constitutions by the use of ill-fitting lenses sold under wickedly false pretences. If any one imagines the picture overdrawn let him place one or a pair of improper cylinders before his eyes, thus putting himself in the condition of an ametrope needing correction, and see how long he can wear them without experiencing a general upheaval of his physical and temperamental balance. In the practice of medicine there is but one field for the optician, and that is the filling of the oculist's prescription; precisely as there is but one field for the druggist, to the same end. When either undertakes to prescribe the public health will suffer by that much. Let us then in the future avoid even the semblance of aid or comfort to the meretricious practices of the "optometrists."

III. *The Advertising Eye Doctor.*—The magazine-advertising quack has bled and blinded many a credulous victim. Happily the business appears to be on the wane, but it is still in evidence and a recrudescence of it would not be surprising. Every oculist from time to time sees cases which have been irreparably injured and even completely lost through the neglect of proper care, which neglect, along with fraudulent but expensive treatment, has been the result of everlasting credulity in combination with the plausible, however, worthless "guarantee of cure" by the advertising swindler.

IV. *The White Incandescent Gas Mantle and Electric Bulb.*—Contrary to general belief and the advertisements as glaring as the lights themselves, these modern forms of artificial illumination are a constant menace to ocular integrity. A few years ago I was for some time nonplussed by girl after girl, students of a large female college, appearing in my office with marked conjunctival congestion with its train of annoying symptoms. I could assign no cause for the phenomenon and all treatment seemed unavailing. I awoke from my stupor to find the dormitories and study rooms equipped with incandescent gas mantles. These were replaced and the epidemic vanished. I have encountered many instances since that time. The glaring white light rays, whether entering the eye direct or reflected from the printed page, are irritating and sooner or later a condition simulating snowblindness is likely to appear. This is a menace to the eyes of the unenlightened people which is daily becoming more popular on account of the beauty and brilliancy of this kind of illumination as well as its (unfortunate?) economy of operation. Frosted glass used over these lights or, better still, indirect illumination with the light reflected from suitably tinted ceiling and walls would greatly improve the situation. Shall we advise the public of its danger? And if we do not, who will?

V. *Badly Printed Newspapers and Schoolbooks.*—The poor we shall have with us always, and from now on likewise the poorly printed newspaper. Its perusal is certainly fatiguing and injurious to the eyes, especially by artificial light. But by its very nature and the demands of modern civilized life it is likely that little, if any, improvement can be had in its make-up at this time. The schoolbook, however, can and should always be made to conform to physiological requirements. Too many of these books are thrown together in a haphazard way, without regard to the kind of paper best suited, the length and width of the columns, the size and spacing of the type, and lastly the weight of the volume complete. All of these things have a direct bearing upon the results in the eyes of our youth. Is it anybody's business, and if so, is it not yours and mine, to protect the innocence of coming generations?

VI. *Badly Lighted Schools.*—Modern schools in metropolitan centers are now constructed under the supervision of competent illuminating engineers and experts. Unhappily, however, the proportion of these in the whole country is less than the proverbial drop in the bucket. But with very little expense of time, trouble, and money nearly every old school could be brought more nearly to the requirements demanded for the conservation of our national eyesight. An intelligent rearrangement of desks and seats and small expenditures for

proper changes of window lights and skylights would be an economic investment of the wisest kind for every community. I have taken the trouble to look over some of these old school buildings and speak from personal observation.

VII. *Unsuitable School Desks.*—Since the child cannot be adjusted to the desk, the desk must be adjusted to the child, even as the mountain and Mahomet. The child should sit erect, with head but slightly inclined, and the eyes equidistant from the point upon which the vision is to be focused. Too much inclination of the head will effect a constant determination of blood to the ocular structures, resulting in elongation of the antero-posterior axis and myopia; while any but a normal position will surely impose an unusual strain upon the musculature of the eyes and must ultimately and certainly impair their usefulness.

VIII. *Kindergartens.*—The large majority of young children's eyes are hyperopic, or farsighted. To force an effort of visual accommodation in a hyperopic eye at a tender age, when the tissues are least resistant to any form of strain or pressure, is cruelty approaching barbarism. The sole excuse for it is ignorance of its consequences. The results are seen later when astigmatism and especially myopia appear with their accompanying evil effects upon health and general development.

IX. *Moving Picture Shows.*—I am disposed to think that the modern motion picture is a serious agent in the production of ocular fatigue, with its train of corollary manifestations. If this be true the marvelous growth of popularity of this form of entertainment with its insidious potency for harm will prove a serious problem for the medical profession in its efforts to conserve the public health.

X. *Antipathy to the Use of Glasses.*—This is due first to the vanity of the individual concerned, and next to the former general belief that the oculist desired to put glasses upon every person consulting him. These errors are happily fading away. Even now we sometimes hear the remark of sympathetic friends and relatives "how sad that so young a child should have glasses put upon it." They do not stop to think, or do not know, perhaps, how infinitely sadder would be the consequences if these glasses were not put on. When the people are educated to the point of realizing that a neglected myopia will be likely to turn into a progressive myopia, leading oftentimes to blindness; and that astigmatism and hyperopia uncorrected lead eventually to nervous and physical wreckage, oftentimes for the benefit of the hospitals, asylums, and other financial or eleemosynary institutions; then and not till then, their psychic astigmatism, insofar as it relates to the wearing of glasses, will pass away, and they will betake themselves to the oculists for the cure of their afflictions.

Bear in mind that you, O doctors, are the teachers, for the very word doctor means teacher. And to-day I have given you the text; this time to be taken, if you please, in both of its interpretations; "Where there is no vision, the people perish."

Strychnine in Cardiac Arrhythmia.—J. Hay states the chief value of strychnine lies in its tonic action on the nervous system and on the vasoconstrictor and respiratory centers. In cardiac asthma, Cheyne-Stokes respiration, and the starting dreams of cardiac patients due to slight asphyxia strychnine is invaluable because of this action.—*Liverpool Medico-Chirurgical Journal.*

A NEW METHOD OF VACCINE TREATMENT AND PREVENTION OF SEPSIS.

By CHARLES H. DUNCAN, M.D.

NEW YORK.

Healthy tissues either resist disease or tend to develop such resistance. This is the fundamental principle of health, and, consequently, of life. The resistance to disease that is brought about by the forces within the body is manifested when the patient recovers without any medication, by the process of what is called "natural cure." Each disease has a definite action on the tissues of the body; the corresponding reaction or resistance to disease is also definite, individual, and especially adapted to resist that particular disease. Not only do healthy tissues tend to resist disease, but healthy tissues tend to resist the action of drugs or poisons. The inception of this idea of natural therapy is the foundation on which the science of vaccine therapy is being built up.*

We have such a firm grasp of the principle of vaccine therapy that it is confidently prophesied by many that we have only to isolate a causative microorganism to secure its vaccine or curative agent. Pasteur said: "The day will come when it will be possible to eradicate infectious diseases by vaccination." This prophecy is being rapidly fulfilled.

"Vaccine is a substance derived from bacteria which, taken into the body fluids, is capable of developing or exciting resisting substances." The reaction in the tissues that is brought about by the action of toxic substances on healthy tissues develops, or tends to develop, resisting substances or antibodies. This resisting substance, if there is sufficient, is the cure for the corresponding disease from which it is derived.

The writer is developing a method of preventing and curing sepsis. The cure consists in giving the patient crude pus from his own wound by the mouth. The prevention is effected by putting the discharge from a fresh wound in the patient's own mouth. To get some idea of the possibilities of this method of curing and preventing infections, we have only to direct our attention to the dog and cat and other animals that lick and cure their wounds. This is the oldest method of wound treatment the world has known, for animals have always licked and cured their wounds since the morning and evening of the sixth day of creation.

The only place where, as a rule, a cat or dog has bad infections is on the head, which it is impossible for them to lick. If the pus from their head wounds is placed in the mouth, they will recover from their head wounds as they do from wounds which they can lick. In licking their wounds, they place the autogenous vaccine in healthy tissues away from the seat of disease, and develop specific antibodies in the serum. This is Nature's method of curing an infection. It is the simplest and the best method of curing infection.

The criticism of this method as crude is unjustifiable, for, with a skilled appreciation of the nature of the infection and the response of the individual, the dose can usually be fairly accurately gaged and readily confirmed by experiment. There is no subject in medicine where there is as great a differ-

*The writer is aware that many of the views expressed in this paper contradict much that is held to be true by those best qualified to judge in such matters. His claims, however, are based on clinical results, the court of last resort in determining questions relative to the therapeutic value of any medical preparation.

ence of opinion as the subject of dosage. And in this comparatively new field of therapy it is a subject of which we know little. It may be mentioned, in this connection, that the dose of vaccines by the method now in vogue is (to a large extent) experimental, and that the majority of authorities, in giving the vaccines, are guided by the clinical symptoms of the patient.

In giving pus by the mouth it is difficult to say just what the fatal dose would be. Parke, Davis & Co., in their Detroit laboratory, fed a horse a quart of heterogeneous pus with scarcely any appreciable results. The only physical sign manifested was a rise of one degree and a half in temperature.

After experimenting two and one-half years at the Volunteer Emergency Hospital, I find the crude material, or discharge from the wound, is especially prompt and curative in the earliest stages, and in the later stages when the infected area is well walled off. A dilution of discharge from the wound is more prompt in its action in the intermediate stages. This should be given also when there is a prolonged or bad negative phase by either the dose being too large, too often repeated, or by the patient being especially susceptible. I have never seen the necessity of giving the dilution in the earlier stages.

Prescription for a Fresh Wound.—If the crude secretion from a fresh wound is given by the mouth soon after the wound is made, and repeated every four hours until the danger of infection is past or a negative phase sets in, it will tend to stop or abort infection in its incipiency. The first inoculating or parent microorganisms multiply extensively before we can microscopically determine their presence or before pus can be seen.

Put a drain to the deeper structures, where possible, and dress the wound every 12 hours, giving the patient the discharge from the wound by the mouth. This is collected from gauze or by soaking the drain in a small quantity of water—an ounce—or washing the secretion from the gauze by means of a water bottle and giving the mixture to the patient by the mouth in dram doses. We thus steal a march on the developing microorganisms in their early stages of development, and hence antibodies are formed in the tissues early that will prevent or stop further proliferation of the bacteria or an extension of the disease. The comparatively few microorganisms are at this time rendered an easy prey to the phagocytes; the system at this time will not be weakened or taxed by the disease; at this time few of the phagocytes have been destroyed; few generations of microorganisms have taken place, hence they are not so virulent as they would be later; those in the wound are easier overcome by the phagocytes, and the wound goes on to healing with no appreciable evidence of sepsis.

Without depreciating in the least the value of aseptic and antiseptic surgical treatment of wounds, the writer offers the autoseptic vaccine treatment of wounds as a means of resisting a microbic invasion (by raising the power of the serum, and increasing the activity of the phagocytes, by the action of specific antibodies) *earlier* than any other known method. "It must be admitted that there is much we do not know in connection with the healing of wounds. This has been demonstrated during the past few years by an enormous amount of clinical experience, for at times, when the most rigid aseptic technique has been employed, the wound becomes septic, and in accidental wounds, where infection is expected or invited, the wound often heals by first intention." Autosepsis does not interfere with either of the established methods of wound treatment, but offers an additional safeguard against infection when it is properly employed. Stress has always been laid on the fact that vaccines should be given early, and in no other way can they be given as early as by this method.

The following is but one of many illustrative cases could be cited:

Henry R., 45 years, applied for treatment January 20, 1911, at the clinic of the Volunteer Hospital. In falling he ran a splinter of wood from a rotten board in the back of his right wrist. It was an inch long and from ⅛ to 3/16 of an inch thick, half the thickness of a lead pencil. It was decided to perform an experiment in this instance and the writer asked two of the internes, Dr. Dietrich and Dr. Kirsch, to witness it. In this experiment practically every known rule of modern aseptic surgery was violated, and the best results followed. Nothing was cleansed or sterilized. The instruments used were a scalpel, an artery clip, and a pair of tissue forceps. These were taken from a pocket case of one of the assistants and used as they were. The wound was opened with the scalpel after a futile effort to withdraw the splinter with the artery clip and forceps. It was taken away in small pieces. Time consumed, about ten minutes. First, the wound was not washed or sterile; second, the surgeon's hands were not sterile; third, the three instruments were not sterile; fourth, the suture and the needle were not sterile; fifth, the gauze covering the wound was not sterile; sixth, the wound was placed in the mouth. After the sliver was removed the patient was told to suck the wound vigorously for ten minutes. Then a very superficial suture of silkworm gut was put in place, but the skin flaps were not drawn tightly. A flap of unsterile gauze was placed over the wound and held with a piece of tape. The tape was tied in a bow knot, and the patient was instructed to loosen it and suck the wound every few minutes, especially when he felt any tickling or irritation in it. He was told to return to the hospital at any time if it gave him trouble, but to return at any rate in six days to have the suture removed. He did not return for two weeks and an orderly was sent to look him up. He stated the reason he had not returned was there was no necessity for returning; that the wound healed all right. He was told to return and have the suture removed. He said, "that's all right, I took that out with my jack-knife."

Prescription for Intermediate Stages.—This prescription should also be given for a prolonged or bad aggravation. The crude autogenous pus by the mouth is curative during the intermediate stages, but it takes longer for the pus to disappear; at times pus has not disappeared for ten days. It is for this reason that the writer prefers the dilution during the intermediate stage. The manner of diluting the dose used in developing this treatment is as follows: Place the dose of pus obtained as described elsewhere in an ounce bottle of water. Give this a prescriptive 25 raps against the palm of the left hand; this will thoroughly mix the ingredients. Empty this out of the bottle but retain about half a dram and proceed to fill the bottle up and shake in the same manner for the second dilution. In this way make from six to ten dilutions, and the last is given in the following manner: One-third of the

bottle's contents is placed in the patient's mouth and he is told to hold it there about five minutes. In an hour the second one-third of the bottle's contents is placed in the patient's mouth and held for about five minutes. In another hour the third and last of the ounce is placed in the mouth in the same manner. The patient is told each time to gargle it so that it will come in contact with the tonsils before swallowing.

"In considering the functions of the tonsil," Dr. Bryan D. Sheedy says (MEDICAL RECORD, September 25, 1909), "we must take into consideration and study carefully the teachings of Goodal, Wood, Wright, and others, all practically agreeing (1) that the tonsils possess phagocytic properties; (2) that the lymph currents from the mouth and nose converge toward the tonsil; (3) that the lymph passes into the cervical lymphatics through the tonsils. Some observers have noted that foreign particles pass with the lymph current through the epithelium lining the crypts of the tonsil, but that living bacteria remain in the crypts. When we consider the location of the tonsils above described, generally spoken of as Waldeyer's ring, we are forced to the conclusion that this circular fortification of secreting tissue was not erected without some good purpose in view. This becomes more apparent when we stop to consider that, while all roads at one time led to Rome, all channels, whether over or under the mucous membrane, lead toward the tonsil. Food laden with bacteria on its way to the stomach is forced against some portion of the tonsillar ring by the muscles of deglutition. Food ejected from the stomach is also forced against it and the millions of bacteria passing into or out of the body through the nose and mouth pass or come in contact with this fortification. One investigator pointed out that bacteria entering the crypts of the tonsil remained there, while their toxins passed on into the blood current via the lymph channels, and those toxins in the tissues, or by their presence in the circulation, stimulated the opsonins or resisting substances, thus developing what we call immunity."

Prescription for the Later Stages, or When the Area of Infection Is Well Walled Off.*—From one to five drops of pus from the patient's wound are caught in a teaspoon and covered with a little granulated sugar, for mental effect, and given to the patient as a dose; three doses are given one hour apart and the medication is then stopped. The dose is made up of a drop or two of the thick, creamy pus, together with a like amount of the thin, serous secretion, if there is any, and the same amount of a light curettage from the side of the wound.

In curing acne vulgaris by this method, the dose is usually the contents of two or three small acne pustules, either covered with sugar or mixed with an ounce of water. The patient is told to gargle and swallow this. An aggravation will at times follow.

There are no set rules for determining the different phases of the disease; the condition of the patient will be the guide to determine whether the vaccine should be withheld or pushed. It has been the writer's experience, however, that the majority of cases respond to the tenth dilution given once a week thereafter. Always warn the patient that the first dose may make him temporarily worse. The use of the dilution may occasionally be required in chronic suppurative conditions.

In curing a number of cases of acne vulgaris, I have used slightly varying methods and obtained good results in each. In one case I could not obtain pus enough to see that there was any. In this case I grew a culture on agar slant, diluted it with an ounce of water, gave it to the patient to gargle and swallow, and a cure resulted.

If the best results are to be obtained after having given the patient the autogenous pus, either in crude form or diluted, the patient should be watched carefully for a change in his condition. When improvement sets in do not give any more till the improvement ceases, when a fresh dose is made from the wound as before, and given in a single dose; or, if the dilution is used, give four doses. It should be given as soon as made, always taking a fresh supply from the wound as it is needed. The length of time before another dose is given necessarily varies with the individual.

The writer has endeavored to obtain an aggravation in some of his milder cases by giving ten drops of pus by the mouth, and has obtained none. He succeeded, however, in others, and it was very annoying to the patient at the time. In but one very serious, apparently hopeless, case was there any danger. The patient was so very weak that he had scarcely the strength to set up a reaction, and we had to work with him for some hours before he was out of danger. This patient had an aggravation by my giving him one drop of pus daily for three days. This is the only serious result that I have ever had. Give it in comparatively big doses and results will certainly follow, either aggravations or ameliorations. When either set in stop. There must a certain period of time elapse after administering vaccines, and giving living virus by the mouth I find to be no exception in this regard. If a bad or prolonged aggravation is obtained, give the dilution. If you should get an aggravation (I have not found it troublesome except in severe cases) hail it with delight. Then simply wait patiently until the amelioration sets in. When an aggravation is obtained, the patient will tell you the medicine made him sick. The symptoms most frequently elicited are as follows: The *wound pains;* the patient is sleepless, some vomit, others complain of headaches, etc., etc. Often there is no appreciable aggravation; the first evidence of improvement generally is the patient will say he feels better; his clinical symptoms improve, coincident with the discharge becoming thinner. This is a favorable symptom and no more pus should be given as long as the discharge is thin. If the discharge become thick again, give another dose. Usually the remedy acts very quickly and results can be seen in from one to two days. The writer would like to hear the reports of others along this line, and of their efforts to cure other diseases by giving the autogenous products of disease by the mouth. The simplicity and ease with which sepsis can be cured in this manner bring it within the reach of every physician to test it for himself.

The possibility of autoinfection has been considered, but the known ability of the mouth and alimentary canal to take care of the pyogenic microorganisms is depended on to prevent infection from this source. But, in view of the fact that this is a feature that may receive adverse criticism, we will dwell on it for a moment. Many pathological micro-

*The writer has cured many of the most pronounced advanced cases of sepsis it is the lot of the surgeon to meet by giving the patient pus from his wound by the mouth. The most remarkable cure he has ever seen in medicine has been in curing septic conditions by this method.

organisms have been found in the mouth of healthy individuals. Our food is germ laden and we take into the body by the breath daily millions of germs. We surgeons believe that the slightest touch of our sterile hands to an object that has not been sterilized will render them septic; that is, will place on them pyogenic microorganisms that will cause the wound to be infected, if they should in any manner come in contact with it. In view of this fact, what may be said of the dangers that constantly beset the chronic finger nail biters who constantly keep in the mouth a choice collection of germs gathered throughout the day; or children—especially the street waifs—who place everything they get in their hands (even from the very gutters) into their mouths? What must be said of the dangers which beset the lower animals, who lick their wounds? They place in the alimentary canal virulent pathological microorganisms.

The opsonic index is raised by the placing of pyogenic microorganisms in the mouth. This has been demonstrated a number of times on patients in the Volunteer Hospital, where the writer is attending surgeon.

Abundant clinical experience has demonstrated the fact that a wound infected with staphylococcus, streptococcus, colon bacillus, or any combination of these, will heal quicker and better when the discharge from it is placed in the mouth than by any other medication. If there is reason to believe the wound is septic, then it is the physician's duty to assist the patient in getting the discharge from the wound in the mouth if he would cure the patient in the quickest and best manner possible. If the wound is clean, placing the discharge from it in the mouth will do no harm. The pus-producing germs that are in the mouth develop specific antibodies in the tissues.

Medical writers of all ages mention that cures have been made along the line of organotherapy. Dr. Wm. H. Morley of Detroit, says: "Organotherapy was well known to the ancients and enjoyed peculiar respect in the middle ages. It needs only to be recalled that one writer prescribed internally and externally the liver of the mad dog to the person who was bitten, and one advised for scorpion bite the oil in which the scorpion had been killed; that one applied snake bile for cure of snake bite, and many more of the same kind."

Lux, the founder of isopathy (1823—a system of medicine that consisted in giving the products of disease to cure the disease), might be cited as a pioneer in curing sepsis in this manner; but Lux did not recognize pus as pathological; he considered pus as physiological, or as necessary for wound healing. Lux called pus laudable, so he cannot be credited with curing a disease he did not recognize as such. Again, Lux failed to recognize the all-important feature of this system of medication, that the products of disease to be most curative must be autogenous. For this reason, isopathy passed into history until the writer took up the autogenous feature, in connection with isopathy, and cured sepsis by placing autogenous pus in the mouth, and in the light of modern medical research proved its value scientifically with the opsonic index and in the clinic. This is improved isopathy; this is scientific isopathy. Lux found, for a time, the key to the situation, but lost it eventually because he did not recognize pus as pathological and the great value of the autogenous product. Practically the same thing may be said of Swan. Swan followed in Lux's footsteps and made the same mistakes. The writer has proved pus by the mouth is curative in sepsis and believes, in doing so, he opened the way for the cure of many other diseases, and would here make a plea for a further extension of the usefulness of this idea.

The immortal work of Wright and Douglas in curing infectious diseases by vaccination has been welcomed by the medical profession as being one of the greatest therapeutic advances in the history of medicine. The writer believes the greatest thing they discovered is the fact that vaccines, to be most curative, must be autogenous.

The method of curing sepsis that the writer is developing is more curative, more convenient, less dangerous, less costly, and simpler than the method developed by Wright and Douglas, for the following ten reasons:

1. We are warned by many high authorities of the danger of anaphylaxis in giving repeated inoculations of vaccines hypodermically. Anaphylaxis enters into the hypodermic method of administering vaccines. Anaphylaxis does not hold in the method of giving living autogenous virus by the mouth.

2. Vaccines lose in therapeutic value by heat, as in sterilization. This does not hold true in giving pus by the mouth. It is the nearest endotoxins or the fresh toxic substances from the *live bacteria* that are most potent or curative.

3. Vaccines lose in therapeutic value by being grown in culture media outside of the body tissues. This does not hold true in giving living autogenous virus by the mouth.

4. Vaccines lose in therapeutic value by time. It takes from 24 to 72 hours after the pus is seen in the wound before the Wright and Douglas vaccine can be administered. In the direct method the patient may be given the vaccine from the wound by the mouth immediately, or as soon after the wound is made as the physician may think necessary.

5. The therapeutic value of vaccines may be lessened by extraneous matter, foreign bacteria, or slight error in technique. This danger is a live one and great care must be exerted that it does not occur. Anyone who has attempted to prepare vaccines by the method of Wright and Douglas knows this danger.

6. Vaccine treatment by the Wright and Douglas method is not always within the power of the patient to secure, especially of poor people and people living outside of the cities. The cheapness of the direct method places it in the hands of everyone, however poor he may be.

7. The Wright and Douglas method of preparing vaccines is not always convenient. The writer developed the fact that the specific for the infection is in the wound in the very form nature intended it should be taken. Wherever there is an infected wound there in the wound is the cure, always at hand ready for use. This cannot be said of any other method.

8. The Wright and Douglas method requires a skilled pathologist, one on whose report absolute dependence can be placed. This is not always easy to find. My method requires no pathologist.

9. The Wright and Douglas method requires a well equipped laboratory with culture media, culture tubes, ovens, heat, thermostat, microscope, hypodermic syringe, needle, antiseptics, etc., etc. The method of curing sepsis here described requires nothing but Nature's instruments—our fingers.

10. In the Wright and Douglas method there is danger of an embolus or an air bubble, as there is in all hypodermic injections. There is no danger from this source in the writer's method. This is the best method of giving vaccines to cure sepsis, and possibly many other infectious diseases. It is a true vaccine, and true cures are made by its use. The vaccine made according to Wright and Douglas loses in therapeutic value by the process of preparation. Approximate cures only are made by their use.

When nature cures a bad infection it is by the aid of autoinoculation or the escape into healthy tissues of the toxic product of bacteria that is usually in pus. The various elements of pus also escape into healthy tissues in autoinoculation. The writer employs *identically the same material unchanged that nature employs in effecting a cure.*

Dr. Clive Riviere says, in substance, in The Proceedings of the Royal Society: "Autoinoculation is the escape into healthy tissues of the toxic product of bacteria developed during the course of the disease. Autoinoculation may be assisted by hyperemia, as: heat, in fomentations; massage, as in friction; Bier's hyperemic treatment; stimulating lotions locally applied; medication that acts directly upon the part involved. As soon as the invaders land there is a call for more blood, more plasma acts, destroying them both by chemical process (oxidation, hydration, and, dehydration), and by the action of the specific antibodies. The leucocytes rush out to ingest the foe. If this is insufficient, antibodies are formed in response to the toxins carried through the body in the blood stream and the resistance of the plasma is thereby increased. Nature was the earliest vaccine therapeutist.

"In assisting Nature by induced hyperemia, we have several natural processes to study and imitate. First, irrigation of the infected area by plasma and leucocytes, and this of itself may be enough to cure a mild infection. Second, autoinoculation, or washing of the bacterial products into the blood stream to stimulate in the tissues the formation of antibodies to the invading microorganisms. We are all vaccine therapeutists, as annoying as it may be for us to realize it. It is this natural vaccine therapy that was exploited with success by the time-honored custom of applying hot fomentations, etc., to the inflamed area. By this means not only was irrigation assisted but such irrigation, of itself of value, necessarily helped to an increase of that autoinoculation on which the improved resistance of the body depends. Such an effect is obvious, as far as the hyperemia is concerned. In the application of hyperemia, the influence of the physician has been solely in the direction of irresponsible irrigation, but nature's armamentarium contains in addition the weapon autoinoculation, a weapon to be brought into use where irrigation alone has failed. The physician has neglected this weapon; he has been an irrigator pure and simple. To be sure, autoinoculation has necessarily occurred as the result of this irrigation, but has he directed it? Has he applied his fomentations at such intervals that time may be allowed between for the formation of antibodies? Has he calculated at what intervals he should autoinoculate his cases to maintain most successfully their toxic immunity? As a matter of fact, he has done none of these things."

In conclusion, I hold that the benefit to humanity that will result from this method of curing and preventing infections is inestimable and will go on to the end of time. It opens up an entirely new field of thought pregnant with promise and possibilities for many diseases.

It is the simplest method of curing bacterial infections; it is the oldest method of curing bacterial infections; it is Nature's method. This method of preventing and curing bacterial infections is within the reach of every one.

It is as convenient in the field or in the camp as in the city. In the frozen north or in the tropics the cure is always at hand in the form adapted by nature to be taken. It is obtained by the highest and the lowest alike, "without money and without price."

233 Lexington Avenue.

SOME COMMON ERRORS IN THE TREATMENT OF DIABETES.

By HOMER WAKEFIELD, M.D.,

NEW YORK.

The intelligent application of extensive practical knowledge of a disease to its treatment unfortunately does not appear to be the faculty of all therapeutists. The reasons for this are many, but perhaps the most frequent are wrong concepts of the disease treated, erroneous ideas of the state of health, to which restoration is sought, and, finally, inadequate facts as bases for logical conclusions in both physiology and pathology.

I have taken diabetes as an illustration of the above postulate, because of the fact that I know of no disease which better expresses and exemplifies it than this syndrome, which is productive of so much suffering to the human race, and is at once ordinarily so unproductive of therapeutic results which are creditable to the physician, *per se.*

Diabetes, as it comes to the city consultants, generally is well advanced. The previous physician in charge has usually exhausted his resources and the case has progressed into an advanced stage. Not infrequently the patient comes with the absence of an extremity which has had to be amputated as a consequence of a preestablished gangrene. The general circulation of the economy has been thus seriously interfered with and later therapeutic efforts are correspondingly curtailed. The present critical survey of such cases is not penned with a view of hostile criticism but rather as of a constructive nature, and with the sincere hope that the earlier treatment of this dread disease may be thereby caused to be more successful in the future.

The present space will not permit an exhaustive consideration of this disease, and I will, therefore, confine myself strictly to the criticism of several unfortunate errors of therapy which have been thrust upon my attention.

Despite the now well and generally recognized fact that diabetes mellitus is the most severe and pronounced type of acidosis by which mankind is afflicted, I not infrequently meet with cases which have progressed for years under more or less constant medical care, in which nothing, or practically nothing, has been done in way of either prophylaxis or neutralization of the great acidity.

Occasionally I learn that the alkaline treatment has been tried without success and sooner or later abandoned. A critical analysis of these cases is the prime object of this paper, to which will be supplemented some related considerations.

Among the cases in which attention to the chem-

ical reaction has been ignored or abandoned I have noted primarily negligence of the sources of somatic hyperacidity and secondarily absence of the neutralization of same.

Among the first-mentioned group may be enumerated gastrointestinal acid fermentations, the excess ingestion of acids and acid-forming foods, and finally tetanoid states of the peripheral tissues, which, owing to emotional factors, have developed first sarcolactic and secondly great betaoxybutyric and diacetic acidity.

A misconception of the normal status of the body has led some to administer alkalies regardless of the neutralizing effect, and often shifting from an excess to none at all and conversely, no index being used to determine a definite effect.

The fact that the body equilibrium is not far from the neutrality mark chemically is attested by the fact that the blood exhibits but a slight preponderance of alkalinity, while the urine is normally not strongly acid. Thus the administration of alkalies should be carried only to the extent of slight urine alkalinity, then allowed to recede into slight acidity. An alkaline excess will develop thirst and other unpleasant symptoms even in the healthy and is not a desirable state for a diabetic.

There is no such thing as producing a self-perpetuating neutrality in any manner, but it is absolutely necessary to maintain one from day to day by the continuous administration of alkalies, which have to be carefully graded to meet the varying demands of the economy. Painstaking indexing from day to day to restore the chemical equilibrium of the body is required as a part of the daily series of unremitting readjustments of new equilibriums of the chemical reaction.

The writer's preference among the alkalies is for the better grades of sodium bicarbonate. Magnesia products have been tried and abandoned as far inferior despite the eructations of CO_2 following the intake of the soda into an acid alimentary tract. It is always administered into an empty stomach a half hour or so before meals from one to three times a day and from a half to a heaping teaspoonful as required in individual cases, and never during digestion, except in emergency as a neutralizing agent for gastrointestinal hyperacidities of fermentative origin. Those before meals are regularly administered in water as hot as can be sipped, for general chemical and physical reasons. The before breakfast doses are regarded as the most important in the day and should be the last to be stopped when reduced quantities are administered.

When larger and more frequent doses of alkalies are demanded to attain neutrality than is acceptable in the form of sodium bicarbonate. Vichy Celestins may be supplemented.

Acids and acid-containing and producing foods and beverages are always as far as possible excluded from the diet by the writer. Sugar, syrups, sweetened foods of all kinds, malt food and beverages, in all stages of the malting process, are most harmful, owing both to their great fermentability and to their chemical nature as invert sugar products. In this class are included all products which we know under the names of maltose, dextrose, glucose, and the liquid and powder preparations which are offered as infants' and invalids' foods, beer, malt tonics, ales, porter, stout, etc.

Diastatic (sugar-splitting) enzymes have probably done the greatest harm, for through some reprehensible misconception of the nature of the incapacity of the system for carbohydrates in general, such enzyme preparations have been actually commended to the profession for diabetes by men of acknowledged authority in the medical profession. Despite that at least a great many physicians know the harmfulness of all sugar and malt products in this disease.

A moment's reflection as to the excessively acid status of diabetes mellitus and to the associated fact that the inversion of cane sugar and starches is always an acid process, and we have forced upon us the conclusion that inversion, by virtue of the excessively acid state of the system, is already too rapid and excessive in the diabetic, rather than deficient, and we have need for slowing rather than hastening that process. It is obvious that the prediastized foods and beverages and all diastatic ferments ingested with foods, by over-hastening and producing inversion and enzymic change in carbohydrate foods (sugar and starches), precipitate them too rapidly and abruptly upon the sluggish metabolic processes, resulting in excessive elimination (glycosuria), but yet more damaging, perhaps, to the body is the hyperglycemia, which always is pernicious, but to which I must not digress here.

Conversely to the above the diabetic should ingest his carbohydrates in the most rudimentary and low concentration forms. Among cereals, oatmeal, whole wheat, whole Japanese rice, etc., should replace white flour, white rice, etc. The green vegetables, with their higher percentage of cellulose and other excrementitious matters, are preferred, whereas sweet potatoes, beets, parsnips, carrots, etc. are proscribed. Irish potatoes are much better tolerated when baked and the skins are eaten with the pulp.

The sweeter cereals like barley are not as wholesome for diabetics as the unsweet ones. In general civilization has brought no good to the dietary of the diabetic. The nearer to nature the better.

The hyperesthesia of the general tissues in diabetes and the consequent predisposition to their precocious and excessive reaction to all manner of perturbations of life should be an indication to the physician to as far as possible protect the patient from all disturbing factors and, moreover, to retard or inhibit all exciting and stimulating influences.

Sadly has this rule been broken by medical advisers. Cases have come to my observation in which unlimited quantities of strong coffee have been allowed, even during the night or at very early morning hours, thus by its caffeine content producing an exacerbation of the general hyperesthesia of the disease which has continually necessitated direct narcotic administration for its amelioration.

Diabetes is a pathological state that involves a sluggish state of metabolism, but unlike other submetabolic states it does not necessarily involve somatic suboxidation. Oxygenation may be normal or supernormal, yet the high avidity of the acids of the disease diverts the oxygen from other utilities and animal processes and principally tissue syntheses suffer. The diminution of urea and corresponding excess production of ammonia in the urine should be recognized as a disturbance of the metabolic functions.

I have not for many years given saccharin as-

a substitute for sugar as a sweetening agent. In my experience it acts toxically in all cases and is, if anything, more harmful than carbohydrate sugars in diabetes. In 1901 I tested saccharin as a sweetening agent (substitute for sugars) in cases of excessive gastric fermentations, including my own person, with the result that it was abandoned as the worse of the two evils.

The mental attitude of the diabetic is of great importance and should never be neglected by the attending physician as beneath his notice. Any man or woman who is above giving attention to any bodily function should lose no time in giving up the practice of medicine to others who are better disposed to bestow upon it that which is indicated for a betterment or a cure. The time has gone by when a doctor can ignore that which he is not fond of. To turn patients off with ridicule of their mental distresses, depressions, hyperesthesia, etc., now, is to turn them to "Christian Science," to "New Thought" and kindred cults where at least this feature of their cases will receive exclusive attention and if other factors have already been eliminated a cure may result to the credit of Christian Science and discredit of the physician!

The personal equation is too often neglected in diabetes, and such neglect has led to many cases of unsuccessful results. To favor success derangements of all organs and functions of the body must be located, interpreted, and corrected, however far removed (supposedly) from the diabetic process.

Sedentary habits are absolutely incompatible with normal metabolism and thus are incompatible with diabetes. Exercise of the tissue in one form or other must be adapted to all cases. Even the passive exercise of massage and Swedish movements should be administered to the bedridden. Calisthenics, rowing machine, and other gymnastics should be skilfully adapted to walking cases. Neglect of these physiological requirements serves to determine such cases to the cults, osteopathy, nature cures, etc., and in the end they get them always at the expense of neglected factors. And after the other (medical) treatment cures are actually obtained, on supplying the broken spoke in the therapeutic wheel, they complete the cure.

It is not because any of these cults and irregular methods are more efficient than the armamentarium of the physician, but because it is that the physician is "above his job." He abandons a rich field of therapeutic resources for ideals which his generation may never see realized, if they ever are. He occupies himself with dreams of sifting all diseases down to narrowed definite and specific entities and of finding a specific remedy to combat each one, and while he is wasting his time waiting for Behring, Ehrlich, and lesser lights to perfect serums, vaccines, etc., to antidote disease, and administer poisons which will kill parasites without proving worse to the host that did the parasite, all irregulars are thriving as they never did before, and the position of medicine in the regard of the public is sunken lower than at any time since the days of Hippocrates.

The physician appears to be losing his cue and his nerve. Day by day the physician sinks lower and medicine is passing more and more into oblivion. More and more he neglects the demands of his cases until they pass into the care of the cults or irregulars, or to the surgeon for the separation of the uncontrolled pathological processes from the remaining uninvolved body. The surgeons, in recognition of the incapacity of the physician to utilize what has been considered a medical stage of many diseases, now demand that the cases be delivered to them for exploratory section and excision in the earliest stages at which they reach the physician to save time otherwise lost.

The successful treatment of the diabetic, more than any other with which I am familiar, demands intelligent cooperation on the part of the patient. This is not possible when he is kept in ignorance of the nature of his disease and treatment. There is little chance of a patient becoming dangerously wise by so doing. The more the patient learns of his disease the more he realizes what a big subject it is and how very great must be the physician's knowledge which he must continually draw upon, and the more he appreciates his aid.

My own observation has taught me that a patient who is given liberal ideas of disease, and corrective therapy, and is not turned away in ignorance when soliciting information, is not prone to turn to the cults or irregulars, and especially does the mental attitude of the Christian Scientists meet with logical incompatibilities in those who possess the fundamentals of the physiological and pathological sciences.

Within the boundaries of the profession I have met with the most sadly erroneous treatment of diabetes among the followers of the uric acid dogmas of Haig. Unfortunate, indeed, it is when the diabetic falls into the hands of these men, sees all evil in animal proteins, and thus substitutes therefor the fermentable vegetable proteins and the carbohydrates exclusively.

In general the writer is more partial to low concentration rudimentary forms of foods than to starch-free diabetic foods. He has under his care at the present time a patient whose former physician at once prescribed starch-free bread and sanctioned sugar-sweetened foods with few, if any, limitations, and the patient is an advanced case, having already suffered the loss of an extremity owing to diabetic gangrene.

In conclusion I will be glad if the above epitome of instances of cases of diabetes mellitus which have come to me from other practitioners will lend aid to the family physician who sees these cases generally in advance of the consultant. The early work must be improved or the ultimate work will be unsatisfactory. Many of these cases can easily be cured when taken in time and given the right kind of treatment. The earlier the case is received the more necessary is a thorough survey and analysis of the etiological factors for a correct application of corrective therapeutics.

To fight the disease, fight the acidity to the point of neutrality only, but not only the ready formed acidity, but the deranged processes which are generating it to excess either from ingested foods or degenerating tissues. Thereafter correct living is the key to subsequent normality.

Salicylate of Soda and Iron.—H. Drinkwater states that he has been in the habit of using a mixture containing salicylate of soda and liquor ferri perchloridi, which he has found very useful in rheumatic conditions associated with anemia, and especially in a kind of sore throat which appears to be of rheumatic origin.—*Liverpool Medico-Chirurgical Journal.*

THREE PHASES OF ECTOPIC GESTATION.

By JOHN M. KEYES, M.D.,

NEW YORK.

SURGEON TO ST. BARTHOLOMEW'S CLINIC, ASSISTANT GYNECOLOGIST TO COLUMBUS HOSPITAL.

At a meeting of the Triprofessional Society, held in February, 1910, at the Astor Hotel, New York City, I reported thirteen cases of ectopic gestation which had occurred during twenty months of service at Columbus Hospital. I dealt with the general subject as my background and drew clinical deductions from my findings. At a meeting of the Practitioners' Club of Yonkers, held on March 15, 1911, at the house of Dr. John B. Kouwenhoven, I read a paper on this subject, reporting eight additional cases which occurred between February, 1910, and March, 1911, also at Columbus Hospital. A more critical examination of the records of the hospital shows that we had ten instead of eight cases during the interval. A review of these ten cases bears out my observations as recorded in my previous paper, published in the *New York Medical Journal*, June, 1910.

A study of this topic, drawn from a comparatively large clinical experience, should be instructive to the surgeon as well as to the student. There are phases of ectopic pregnancy which need to be elucidated. The first concerns the bearing that complications have on the surgery of ectopic gestation. In summarizing the ten appended cases I find them complicated as follows:—The second by fibromyoma of the uterus; the third by catarrhal appendicitis; the fourth, while it had no present complications, gives a history of a previous ectopic, occurring six years before, and which was operated on and found complicated by appendicitis and small uterine fibroids; the fifth by interstitial appendicitis and interstitial salpingo-oöphoritis; the sixth and seventh by cystic oöphoritis and the seventh by a twisted tube in addition; the eighth, ninth, and tenth clinically showed febrile reaction, and at operation inflammatory exudates were found involving the appendices. A review of the complications of the thirteen cases previously reported and the fact that such associations are matters of common observation lead me to take issue with the doctrine that the thing to do in extrauterine pregnancy is to get in and get out as quickly as possible. The inference to be drawn from such teaching is that it is our duty to excise the bleeding sac and nothing more. Of course the excision of the gestation sac and the stopping of bleeding are essential, but we must deal also with complications, using the best surgical judgment at our command. If we find septic inflammatory conditions, such as pus tube, diseased appendix, and the like, we must remove them and drain if necessary. If we have fibromyoma of the uterus as a complication a supravaginal hysterectomy may be called for also. The aim of our surgical procedure should be, of course, to reduce mortality to a minimum and to attain the most complete recovery possible. When you bear in mind that your patient is suffering already from shock and hemorrhage and that the operation will add more shock, the necessity for expeditious operating becomes obvious and time-wasting procedures, such as the washing out of clots and so forth, should be dispensed with.

The second phase that I present for critical study has to do with mortality. In my previous paper I stated that the minimum death rate to be hoped for was 2 per cent. To attain it we must have an early correct diagnosis, perfect surgical technique, and an intelligent conception of how to deal with the conditions which lead to mortality. Dr. Hunter Robb reports an operative mortality of 8 per cent. in eleven hundred and seventy-six cases occurring in twenty-five clinics. He reports also a series of thirty-eight deaths, fourteen of which were due to septic infection. Bearing these figures in mind a survey of the twenty-three cases reported by me will show the association of previous and concurrent complicating lesions and thus the problem of reducing mortality becomes somewhat simplified. The two cases of appendicitis with septic aftercourses and the conclusions reached by the independent observations of other surgeons point to one avenue for the reduction of mortality. As we know that one of the causes of postoperative death in ectopic gestation is general peritonitis, I cannot too strongly emphasize the point that where the clinical symptoms indicate an inflammatory condition in the pelvis or in the abdominal cavity, and where after opening the abdomen we find evidences of present or past inflammatory conditions, it behooves us to examine the appendix as well as the pelvic organs, and if it is diseased to remove it, establishing drainage if necessary. We know our mortality from this abnormal pregnancy to be due to hemorrhage, shock, exhaustion, septicemia, general peritonitis, intestinal obstruction, and the usual postoperative risks, such as pneumonia, etc. The first three risks can be coped with by proper medication and the use of normal salt or blood transfusion.

Where ectopic gestation is complicated by diseased conditions, for instance, diseased adnexa, uterine fibroid, or appendicitis, the surgical procedure is clearly indicated. The diseased organ should be removed; and where the surgeon feels that the aftercourse is likely to be septic he should by all means drain through the posterior vaginal wall. The drains when composed of sterile gauze must cover also the cut and raw surfaces. These precautions, the removal of complicating conditions, the establishing of drainage, and the covering of cut and raw surfaces, practically minimize the chances of intestinal obstruction as well as of general peritonitis. The ten appended cases show no mortality.

The third phase of interest is the relative frequency of this abnormal pregnancy. The fact that twenty-three of these cases occurred in thirty-three months, the prevalence of conditions leading to extrauterine conception, and the universality of pregnancy make me feel that ectopic gestations are much more frequent than we had supposed. Undoubtedly many cases escape detection and the patients live without surgical treatment. The inability to judge whether a given case will live or die leads me to advocate immediate operation. The proportion of extrauterine to intrauterine pregnancy is said to be one in two hundred.

I shall dwell on those cases which have interesting clinical features. The pathological work was done by Dr. William B. Noyes and Dr. W. W. Hala. The cases occurred on the gynecological services of Dr. Egbert H. Grandin, Dr. Charles F. Adams, and the author.

CASE I.—C. P. Admitted March 3, 1910. Discharged March 20, 1910. Age 26 years. Married 2 years. Housewife. Previous history negative. Menstrual history:—Menstruated first at 16 years; 28-

day type; 4 to 6 days' duration. Amount small. No pain. No children; no abortions. Present history:—Last normal menstrual period, January 29. For 20 days had vaginal oozing accompanied by pains in one inguinal region or the other and at times cramp-like pains over the lower abdomen. Two days before admission had severe vaginal hemorrhage. Admitted 3 P. M. Pulse ranging from 90 to 94; temperature normal. One hour afterwards was operated on. Curettage and abdominal section. Free blood and clots in abdomen. Right ruptured ectopic. Microscopical examination of mass showed decidual cells, but no chorionic villi. Pulse varied between 78 and 82 until patient was discharged. Temperature normal.

Case II.—C. R. Admitted April 14, 1910. Discharged May 8, 1910. Age 38 years. Previous history:—Had usual diseases of childhood. Menstrual history:—Menstruated first at 15 years; 28-day type; 2 to 6 days' duration. Amount small. No pain. After marriage at times menstruated 7 to 8 days and in large amounts. No children; no abortions. Two months before had cramp-like pains in lower abdomen which continued accompanied by vaginal bleeding for 8 days. Six days later passed clots accompanied by cramp-like pains. Vaginal oozing continued except at brief intervals until she was admitted to the hospital. Physical examination showed the abdomen enlarged, cervix soft and lacerated, uterus enlarged and surface uneven with a mass to the right of it. Pulse varied from 86 to 92; temperature from 98 to 100; respiration was 20. Operation performed 24 hours later. Abdominal section; hysterectomy; left salpingo-oophorectomy; right salpingectomy. Free blood in abdominal cavity. Microscopical examination showed fibromyoma of the uterus, chronic salpingitis, ectopic gestation in right tube, which was eroded. Decidual cells present. Temperature ranged between 98 and 100 until May 8, when it stayed normal. Pulse ranged between 80 and 82 until patient was discharged.

Case III.—A. G. Admitted April 4, 1910. Discharged May 8, 1910. Age 33 years. Married 10 years. Had 2 children, the younger three years of age. Menstrual history:—Began at age of 16; 28-day type; lasted from 4 to 6 days. Amount small. Pain occurred previous to appearance of blood. Last menstruated March 12. Present history:—Began two months previously to have cramp-like pains in lower abdomen, severe in character and more or less continuous. There was vaginal oozing during the same period. Complained of general weakness. Uterus large and soft with masses on both sides of it. Pulse varied from 76 to 84; temperature normal. Was operated on 4 days after admission. Abdominal section. Free blood in abdomen. Ruptured left tubal gestation. Appendectomy. Catarrhal condition of appendix. No drain. Aftercourse uninteresting.

Case IV.—A. R. Admitted June 14, 1910. Discharged June 28, 1910. Previous history:—Six years before was operated on for tubal gestation, appendicitis, and the removal of two small fibroids from the uterus. Last menstruated October, 1909. Present history:—For the past two months had had cramp-like pains in the lower abdomen, vaginal oozing, nausea, and vomiting. Had mass to left of uterus. Operated on 4 hours after admission. Abdominal section. Left tubal gestation (primary rupture). Aftercourse uninteresting.

Case V.—C. M. Admitted August 14. Discharged September 3, 1910. Age 30. Married 10 years; had 3 children, youngest 10 months old. No abortions. Menstrual history:—Menstruated first at 14 years. Period regular; flow 4 to 5 days in duration. Last menstruation July 14, 1910. For the past two months had had cramp-like pains in lower abdomen and in the back; also headaches, chills, and fever. Mass to the either side of uterus. Abdominal section; salpingo-oophorectomy and appendectomy. Clinical diagnosis was ectopic gestation. Pathological diagnosis was chronic interstitial appendicitis and tubal pregnancy. Specimen consisted of an appendix with interstitial changes, a tube and ovary also undergoing chronic interstitial thickening, and a sac about the size of a peach, the serous surface of which was much inflamed. Section showed the contents of the sac to be clotted blood. Microscopically it looked like an ampullar pregnancy and revealed decidual cells, but no chorionic villi.

Case VI.—R. C. Admitted August 11, 1911. Discharged September 1, 1910. Age 28 years. Married 3 years. Had one child 2 year old, and one abortion. Menstrual history:—Menstruated first at 14 years of age. Type regular; flow lasted 6 or 7 days. Pain occurred before flow commenced. Last menstruated July 6, 1910. Had had vaginal bleeding since July 6, 1910. Operated on the day following admission. Curettage; abdominal section. Free blood in cavity. Pathological report (No. 1,233): Clinical diagnosis was ectopic gestation and microcystic oöphoritis. Specimen consisted of an appendix, a tube, and an ovary. The appendix was apparently normal. The ovary was slightly larger than normal, soft, and on section its parenchyme was seen invaded with small cysts containing a bright mucoid liquid. The tube was egg-shaped—5 c.c. long by 3 c.c. in diameter. On section it was found filled with blood clots occupying the entire lumen of extrauterine portion of tube. The fimbriated end was occluded. This is the ampullar type of ectopic pregnancy Microscopical examination revealed chorionic villi and decidual cells.

Case VII.—M. L. Admitted November 3, 1910. Discharged November 19, 1910. Had last child 14 years previously. One abortion. Menstrual history:—Menstruated first at 13 years of age. Type regular. Present history:—Was regular until 2 months before admission to hospital, when she began to have continuous vaginal oozing, accompanied by cramp-like pains in the lower abdomen. Uterus slightly enlarged with a mass behind it. Pains in lumbar region. Three weeks before was curetted at her home for what was supposed to be a uterine abortion. Operated on the day following admission. Abdominal section. Free blood in abdominal cavity up to midway between symphysis and umbilicus. Right tube and ovary removed. Tube enlarged and adherent posteriorly to uterus. (Pathological case No. 1,278). Clinical diagnosis was ectopic pregnancy and ovarian cystoma. Pathological diagnosis was tuboovarian pregnancy. Specimen consisted of a blood clot the size of a walnut, a twisted Fallopian tube, and a cystic ovary. The tube was not ruptured and was occluded. The clot was surrounded by a mass of tissue including the fimbriated end of the tube, adhesions, and the ovary. Microscopical examination revealed no chorionic villi, but areas of clearly marked decidual cells. In this case we had a tubal gestation to begin with and somewhat pre-

vious to her curettage the patient had had a tubal abortion of a still viable ovum, which attached itself to the ovary and the surrounding tissue, causing an exudate to be thrown around it.

Case VIII.—C. S. Admitted November 19, 1910. Discharged December 16, 1910. Age 38 years. Previous history:—Two curettages, the last 18 months before patient's admission to hospital. Six months before had a laparotomy for ruptured ectopic gestation in right tube. Present history:—Menstruation delayed 14 days and then had cramp-like pains in lower abdomen with vaginal oozing and symptoms of internal hemorrhage. Physical examination revealed rigidity of abdominal muscles, tenderness over lower abdominal zone, and a mass posterior and to the left of the uterus. Pulse 92; temperature 100°; respiration 34. Operation:—Curettage and abdominal section. The abdomen was full of clots. Left tube ruptured ½-inch from fimbriated end and it was surrounded by inflammatory exudate and the appendix was caught in this exudate. The tubal mass and appendix were removed; cut and raw surfaces were covered with sterile gauze and drainage established through posterior vaginal fornix. The aftercourse was septic. Pulse and temperature were practically normal by December 14. This is the type of case that calls for drainage and protection of the intestinal coils against adhesion. I feel that the patient's chances of developing general peritonitis or intestinal obstruction were minimized by the surgical practices employed.

Case IX.—R. G. Admitted January 2, 1911. Discharged February 7, 1911. Age 25 years. Married 5 years. Had had one child 3 years previously. Present history:—She had what she thought was a uterine abortion 20 days before admission, since which time she had had vaginal oozing, cramp-like pains in lower abdomen, and at stool she passed clots. Had mass at left of uterus and posterior to it. Pulse ranged between 88 and 112; temperature 99° to 100°; repiration 22 to 24. She was placed on table January 4, 1911, the regular operating day, with a diagnosis of pelvic abscess. After an examination under ether I suggested that we might have an ectopic gestation to deal with. Curettage and abdominal section followed. Free blood was found in the abdomen and a ruptured left tubal gestation. There was considerable inflammatory exudate and the appendix was removed and drainage by posterior section was established, the same procedure being employed as that described in case IX. The pulse ranged from 100 to 140 for 12 hours following the operation and then slowed down. The patient was given the Murphy drip in the Fowler position, eserine, and strychnine. The aftercourse was septic. Temperature became normal after February 4, 1911. These cases fully emphasize my point that diseased appendices should be sought and removed in cases of ectopic gestation where the clinical symptoms as well as the operative findings show inflammatory change complicating the original condition.

Case X.—C. R. Admitted January 11, 1911. Discharged February 14, 1911. Age 28 years. Had had 2 children, the last of whom was born 7 years before. Had had no abortions and had menstruated regularly. Present history:—Menstrual period was delayed 9 days; then she had vaginal hemorrhage accompanied by cramp-like pains in lower abdomen, especially severe over the left side. Physical examination revealed small mass in region of appendix. Uterus was not enlarged, but there was a soft mass to the left of it. Pulse 80; temperature 100°; respiration 20. Operation was performed on the following morning. Abdominal section. The abdomen was full of clots and free blood. Left tube was removed and also the appendix. Inflammatory exudate was around the tube and the end of the appendix was caught in it. The tube was not ruptured and the clot was at the fimbriated extremity. This was another case of tubal abortion. Microscopical examination revealed chorionic villi. The patient had a slight fever for a few days. Her pulse ranged between 80 and 90 until she was discharged.

THE O'DWYER FORCIBLE RESPIRATION APPARATUS FOR CHILDREN.

By JOSEPH O'DWYER, M.D.,

NEW YORK.

The O'Dwyer-Fell apparatus for forcible artificial respiration has been in existence several years and has been used at one time or another in most of the hospitals. Some wonderful results in cases of respiratory failure have been accomplished with this apparatus. If you will permit me I should like to quote from memory the essential details of a case that occurred several years ago at the Presbyterian Hospital.

A male ward patient suddenly stopped breathing; Dr. David Bovaird, an interne at that time, had an O'Dwyer-Fell apparatus handy. He got this going and the patient's pulse came back. Artificial respiration was continued for a couple of hours with the patient in good shape. It was then stopped. The patient's pulse again began to fade until it disappeared completely. Artificial respiration was then resumed, with a return of the heart's action. This procedure was tried two or three times with like results. Life was kept in this patient twenty-four hours; then the doctors, realizing the hopelessness of the case, discontinued artificial respiration and the patient promptly died. Death was the result of a tumor of the cerebellum pressing on the respiratory center. I have quoted this case to show the possibilities of this form of artificial respiration.

The O'Dwyer part of this apparatus consists of a cone-shaped ridged end. This fits snugly into the larynx and has running through it a channel for the passage of air. This in turn is connected with a hollow metal tube curved at right angles and fitted with two external openings, one for the inspired air, the other for the expired air.

The Fell portion of this apparatus is a large bellows with rubber tubing connecting it to the laryngeal portion. The bellows is placed on the floor and worked with the foot. This, it seems to me, is open to serious objections. In the first place the air is not warmed, but is forced directly into the larynx and lungs without any warming medium.

In the second place, while there is a sponge below the tubing, still the apparatus is on the floor and is most likely to blow dust right into the lungs. You can see that these two reasons acquire added importance when artificial respiration is kept up for hours. Under normal conditions of breathing the narrowness of the nasal passages and the bend which the air passage makes in the pharynx serve the useful purpose of freeing the inspired air very largely of its dust, particularly since the latter adheres very closely to the mucus-covered walls of one cavity or the other.

My idea, with a very simple modification which I have devised, is to get the air to the lungs under the most natural of conditions. It consists of a long cylindrical bottle or large test tube. This bottle is half full of water and plugged with a rubber cork. Through this cork two glass tubes are passed. The first one enters the water; the second just penetrates the cork. To the second one rubber tubing is attached, which in turn is connected with a suction valve on a large rubber bulb (taken in this apparatus from an automobile horn). More rubber tubing connects the end valve on this bulb with the laryngeal instrument. The cylindrical bottle is placed in a bowl or large graduate containing water kept at about 110° F. Of course, the principle made use of is very simple. When the bulb is compressed a partial vacuum is created in the bottle. The outside air rushing in through the long tube and passing through the water is both warmed and filtered. After this it passes into the expanding bulb and is ready to be forced into the lungs. While the bulb is compressed the thumb is held over the outlet for the expired air. After a very short interval, depending on the age of the child, the thumb is removed and the air allowed to be expired. Since the air pressure acting upon the inner wall of the thorax is lower than the atmospheric pressure exerted upon the outer wall, every dilatation of the thorax is counteracted by a force corresponding to the difference between the outer and inner pressure. It is obvious that the expiratory contraction of the chest wall is favored by the same circumstance and that respiration almost always stops at the end of expiration.

During the first year of life the average rate of respiration is 44 per minute; at the fifth year it is about 26. According to Grey, the average breath volume in children in the first month is 1,300 c.c. per minute; in the twelfth month 3,000, and between the second and third years averages between 4,000 and 5,000 c.c. You may see from this that a foot bellows would be out of the question with young children. We would, of course, have no way of gauging the amount of air we were giving them at each inspiration, while with this method we can have different sized bulbs and gauge the amount of air we are giving them quite accurately. To a child a month old we would give 30 c.c. or about 1 oz. 44 times per minute. To a child up to one year of age a 2-oz. bulb emptied 40 times per minute would give sufficient oxygen to enable the heart to carry on its work.

The demands for forcible artificial respiration are, of course, limited, but when the demands must be met they must be met promptly, and on our method of meeting them often hangs a life. Some of the following are instances where forcible artificial respiration is urgently indicated: Sometimes in new-born infants; in chloroform poisoning; practically every case of death from chloroform is due to the failure of respiration. Some others are opium poisoning, drowning, and suffocation. There are cases in which a small cerebral hemorrhage presses on the respiratory center, causing death almost instantly. If artificial respiration were tried for a few hours this hemorrhage could be sufficiently absorbed to allow respiration to continue naturally. There are also cases of collapse from the loss of blood and hydrocyanic and carbonic-acid gas poisoning; also in convulsive spasms of strychnine and caffeine poisoning.

The diaphragm is the most important and probably the most typical muscle of respiration. The majority of the shoulder girdle muscles and neck muscles with thoracic attachments have other work besides their respiratory functions. The muscles of the shoulder girdle and the neck, being more distinctly voluntary muscles, are the first to become paralyzed, then the abdominal muscles, and finally the diaphragm. Under ordinary conditions the diaphragm is capable of supplying sufficient oxygen for ordinary purposes. But where there is considerable abdominal distention or where the patient has a pneumonia or pleurisy with effusion then the diaphragm alone is insufficient. When a patient of this type has to take an anesthetic we should always be prepared to carry on respiration by artificial means.

Apnea, according to physiologists, is not the last stage of dyspnea, but that condition in which the blood is so excessively aerated that there is no need for breathing at all. For instance if one holds his breath he will find that he can hold it but a few seconds, and then if he take several short breaths and repeat the experiment he will find that he can hold it for several seconds longer than at the first trial. This is a state of apnea as understood by physiologists. A few years ago it was discovered that when rabbits were kept in this condition a fatal dose of strychnine might be given without producing any effect. When respirations were discontinued and the animal allowed to pass from this condition of apnea convulsions came on even after respirations had been kept up three hours. If respiration were continued, however, for four hours the strychnine must have been excreted or destroyed, as there was no return of convulsions on discontinuing respiration.

This apparatus, with slight modifications, can be used for giving anesthetics for operations on the nose and mouth. The bulb is removed and the rubber tubing is connected directly from the laryngeal portion of the apparatus to the short glass tube that just penetrates the cork. The cylindrical bottle or test tube is then half filled with ether and placed in water at about 110° F. This not only gives us a simple method of warming the ether vapor, but also tampons the pharynx and prevents any blood entering the larynx during the operation.

Antitoxic Action of Iodine in Tuberculosis.—S. Rocci finds that iodine is of value internally in cases of tuberculosis of the lymph glands. He has made experiments to demonstrate this fact in animals. He considers it demonstrated that iodine exercises an antitoxic action against the tubercular toxins. This action is of a chemical nature, since the drug after entering the circulation fixes and neutralizes the tubercular toxins. The experiments made by the author are impossible of explanation on the supposition that the action of iodine is due to the biological production of antitoxins.—*Il Policlinico.*

SIGNIFICANCE OF HORMONES IN INTERNAL MEDICINE.

THE provisional definition of a hormone is that it is a substance formed in a given organ and capable of exerting a specific biological action on other organs, to which it is carried in the blood stream. Some hormones exert a general, others a local, activity. When hormones are produced in excess or in diminished quantities morbid syndromes are set up. The interrelations and indirect manifestations of hormone action are most puzzling. Many of the simplest biochemical activities become still more simplified if regarded as due to the latter. For example, the part played by hydrochloric acid in gastric and intestinal digestion has usually been regarded as settled. This acid, so it has been taught for years, changes propepsin to active pepsin, and before its neutralization in the duodenum is a biological stimulant of the biliary and pancreatic functions. To-day, however, it is asserted that hydrochloric acid simply causes the production of hormones in the digestive surfaces, and these being taken up into the blood constitute the natural biochemical stimuli of pancreatic secretion, and to a certain extent of all the other digestive secretions. The so-called gastric secretion (gastrin) is further a stimulant of the muscle of the digestive tract, an activator of peristalsis.

At a recent meeting of the Verein für wissenschaftliche Heilkunde in Königsberg, Borchhart read a paper on the relation of hormones to disease (*Deutsche medizinische Wochenschrift*, June 8). Incidentally he touched upon certain adrenal syndromes. Adrenalin is used up by excessive muscular exertion, so that in death from the latter cause the organism is bankrupt of this substance, the absence of which is directly responsible for the fatal outcome. Hence, in disease of the suprarenals with diminished production of adrenalin a characteristic state of adynamia results. In high-pressure nephritis there are overaction of the adrenals and adrenalinemia, but the precise connection between the two conditions has not yet been made out. If the renal lesion is responsible by continuity or otherwise for the suprarenal disorders, the latter in turn are doubtless answerable for the arterial symptoms. In diminished functioning of the suprarenals the normal content of the blood in sugar is lessened and hence the alleged benefits derived from glucose in Addison's disease. Conversely in high-pressure nephritis there is an increase of sugar in the blood which does not appear in the urine because of diminished renal permeability. Acromegaly has been shown to depend, at least in part, upon hyperfunctioning of the hypophysis, for it tends to improve if the latter is removed. The opposite conditions of myxedema and exophthalmic goiter are explained by the author as hormone syndromes, due respectively to diminished and increased hormone action. Spasmophilia similarly means a decrease in the hormone production of the parathyroid glands. The over and under-production of several of the hormones stand in close relationship with carbohydrate metabolism. Adrenalin has already been mentioned in this connection, and similar relationships have been noted for the hypophysis hormone (hyperglycemia and glycosemia of acromegaly, the thyroid hormone (hypoglycemia and storage of glycogen in myxedema), the pancreatic hormone (diabetes of pancreatic origin), etc. In discussing the paper, Hofbauer spoke of the close connection between the ovary and the growth of bone and hemopoiesis respectively. The hypertrophy of the hypophysis in pregnancy is believed to stand in definite relationship with the ability of hypophysis extract to induce uterine contractions. It is perhaps taking too much for granted to regard every active principle in the body which acts through the blood as a hormone. Perhaps the only principles commonly regarded as hormones to date are the mamma hormone (Sterling), secretin, the peristaltic hormone, and the pancreatic hormone. These substances defy isolation to the same degree as enzymes. Their action is specific and appears to be localized. Many authorities are not yet ready to apply the term hormone to adrenalin and the active principles of the thyroid, which differ in several important respects from the preceding. In his recent monograph on the internal secretions Biedl uses the term hormone tentatively, while in the main preserving the older nomenclature. The most numerous and varied substances from a given animal may behave as hormones in the blood of another animal, so that even food albumin may be so termed. Again a disease-toxin may be conceived of as a harmone. Unless much care is used, the term is likely to lose entirely its primary significance.

INTELLECTUAL PRECOCITY.

INFANT prodigies in various branches of learning and of mental effort have flourished in all ages. Perhaps these have been most distinguished in music and mathematics. Of late years we have never been without the infant phenomenon in music and there have been several of tender years who have been somewhat remarkable as mathematicians. However, it is not difficult to understand why children precocious in music should predominate, for they are a ready and sure source of income to their parents. People are always anxious and willing to hear or see freaks of any description, and most of the musical prodigies may be numbered in this category. Tom A. Williams has written recently

concerning intellectual precocity (*Pedagogical Summary*, May, 1911) and propounds some interesting views on the subject. He believes that intellectual dexterity is an orderly functioning of mental processes seated in the brain and it is manifest that these will reach excellence best when they are trained by a capable hand during the formative period of early youth. He draws an analogy between the mental processes and the processes of physical development, arguing that as more or less constant exercise and work are needful for the attainment of a perfect or good physical structure so are they needful for the development of mental power. He carries the argument still further and contends that the precocious individual is not necessarily naturally extraordinary but has been deliberately guided to and trained in intellectual or other excellence. In support of this contention the example is cited of John Stuart Mill, who is said to have declared that both in memory and understanding he was considerably below the average of boys of his age; in spite of which his early training gave him what he contends to have been an advantage of 25 years over his competitors in after life. The case of the son of Dr. Boris Sidis is also brought forward, the father having explicitly stated that his boy's apparent genius is due only to the training of his intellectual activities in early life. This statement, however, was made with certain reservations.

Stress is laid upon the necessity for achieving a pleasant "feeling-tone" if one wishes to make the most of the intellectual capacities of a growing brain. It would not seem that the study of Greek would give pleasant feeling-tones to a boy of four, nor the study of anatomy the same to an infant. Yet this is what occurred in the respective cases of John Stuart Mill and young Sidis, and Williams argued that the fact that each boy learned with facility at that age proved that the task was agreeable.

After discussing at considerable length the whys and wherefores of the attainment of mental expertness and mental acquirements by young children, Williams asks the question, "Can a John Stuart Mill or young Sidis be reproduced in any family?" and answers as did Oliver Wendell Holmes: "Yes, if you begin with the grandfather," meaning from the standpoint not altogether of heredity but of attainment and atmosphere. That is to say that the father must be a trained man, and for the father to be a trained man the grandfather must have been so likewise. Williams is of the opinion that learning to think is of extreme importance in the attainment of that genius known as precocity and he defines genius as consisting in the power to maintain at the same time in the mind many impressions and to relate the complexities of these into a generality. It is, he thinks, in its first steps necessarily a capacity for taking pains.

After all has been said that can be said on the subject, the list of infant prodigies who have fairly fulfilled the promise of their youth may almost be counted on the fingers of one hand. As a rule, indeed, those of conspicuous genius have not displayed great application in their youth, nor does it seem likely that had they been compelled to application they would have evinced greater powers or production of brain during their adult years. The history of infant prodigies is not on the whole encouraging, nor was the career of John Stuart Mill so successful as to be a strong argument in favor of the kind of training he underwent. He most decidedly did not wholly fulfill the promise of his youth. One of the earmarks of a genius is originality and the majority of those who have shone in their earliest years have either snuffed out like a candle or have in after life displayed little or no creative faculty. Williams has written a most instructive and suggestive paper, but his pleading does not carry conviction that the teaching of Greek or anatomy to children of four or five would be attended with satisfactory results in the large proportion of instances, either mentally or physically. On the other hand, it may be most emphatically stated that in the routine education of the youth of what is termed the Anglo-Saxon race too little attention by far is paid to the training of the mind, and too much to physical training and amusement. The happy mean is the point at which to aim.

OFFSPRING OF TUBERCULOUS MOTHERS.

The progeny of tuberculous women, the results of gestation on the latter, and allied topics have always been the subject of much argument. Experienced family practitioners still hurry girls who are candidates for tuberculosis into matrimony in the hope of staving off the disease; gestation has similarly been forbidden to married women actually tuberculous; and it has been shown abundantly that such women are much less likely to conceive and more prone to abort than are healthy women. It has been claimed that the progeny of consumptive women, while not actually tuberculous, tend to invalidism and short life, and to psychopathic disease; this notwithstanding that every now and then some sceptic reports that normal children, of full weight and health, are born of women far advanced in the disease.

We are, therefore, in the presence of this inharmonious teaching, well disposed to listen to the 20 years' experience of an authority like Petruschky on these subjects. This author read a paper before the Northeastern German Society for Gynecology last winter (*Deutsche medizinische Wochenschrift*, August 17), in which he said that 19 pregnancies were carefully followed up in 18 women with active tuberculosis. Eleven children were born alive and all reacted negatively to von Pirquet's test. Twenty-four pregnancies in 22 women with latent tuberculosis gave similar results.

The author does not therefore prohibit the marriage of tuberculous women, but if these become worse as a result of conception he advises that the gestation be interrupted at the proper time. He would treat all unmarried women up to the time of marriage and all married women up to the time of conception and all gravidæ with especial refer-

ence to the use of tuberculin. Children born of such mothers he would also treat according to indications. He does not seem disposed, in other words, to allow tuberculosis to furnish anything like an absolute contraindication to marriage, conception, and childbirth.

TREATMENT OF GOUT WITH MINERAL ACIDS.

A GENERATION ago an English practitioner, who was an unattached individualist, created quite a sensation by publishing numerous cases from the ranks of his aristocratic patrons in which reports he always gave the antecedent treatment as prescribed by other notables (whose names he invariably repeated and whose prescriptions he regularly reproduced). His method was often simplicity itself. After a client had consulted some world-famous authority (who stood sponsor for a special therapeutic principle), and had become decidedly worse as a result, our individualist simply reversed the principle of the treatment, and—if we choose to believe him—promptly cured the patient. Apparently he went no further into the rationale of the treatment. Thus if a peer had chanced to consult Sir William Gull for his gouty paroxysms and had become distinctly worse after large doses of alkalies, the individualist merely changed the treatment to full doses of nitric acid, whereupon the patient at once experienced decided relief.

Quite recently Schmidt of Frankfort has advocated the use of hydrochloric acid in persistent high doses for certain cases of gout. But unlike the English empiricist he has a definite reason for this procedure, which, moreover, has its special indications. The treatment did not originate with him, for long ago the discovery was made that gouty patients often suffer habitually from defect of acid in the stomach. The biochemical studies which throw light on this mechanism are too numerous and complicated to be cited in this connection. They naturally involve the entire biochemical pathology of gout and of uricemia; and eventually of all the chronic affections which are found associated with gout.

Without at present going deeper into the subject we may simply call attention to the fact, which the author insists upon, that iodides should be combined with hydrochloric acid in these cases. Alkalies are still the remedy in the so-called uratic diathesis, which, however, furnishes but a fraction of the cases of clinical gout.

PRESENT STATUS OF RADIUM THERAPY.

AT a meeting of the Ontario Medical Association held at Niagara Falls, on May 31, 1911, W. H. B. Aikins and F. C. Harrison of Toronto read a paper dealing with radium therapy. As for the chief diseases in which radium may be used, the authors first draw attention to the fact that Wickham has shown that the word specific as applied to radium in the treatment of disease is incorrect, and that selective action means only that special pathological cells offer an inferior resistance to the action of radium. After pointing out that radium has been employed with much success in the treatment of numerous diseases of the skin, in certain rheumatic affections, exophthalmic goiter, and in many nonmalignant growths, its importance in the treatment of cancer is emphasized. The word cancer, too, is used in its widest sense, to include the whole series of malignant new growths, including rodent ulcer, epithelioma, carcinoma, and all the varieties of sarcoma. With reference to the influence of radium on goiter, they profess themselves as fairly well satisfied with its beneficial action, although their experience in this mode of treatment has been necessarily somewhat limited. The advantages of radium treatment of cancer in comparison with other forms of treatment are summarized as follows: The rays penetrate with facility to the deeper tissues, the apparatus is easy to manipulate, and the technique of the treatment is simple. Where extensive surfaces are involved in the growths the opinion is expressed that treatment by the Röntgen rays is preferable to that by radium. In the treatment of cancer of the breast radium has been used as a preliminary measure to operation and has apparently improved the condition of the operation field. Wickham has stated his conviction that intense preliminary radiation diminishes the malignancy of the operation area. In some instances of deep-seated cancer radium has shown itself a seemingly efficient remedial agent, but Aikins and Harrison, like Wickham himself recommend surgical procedures wherever feasible and likely to be followed by good results. In the more superficial forms of cancer radium frequently has a remarkable remedial and curative action. In more serious cases of malignant disease radium may often be used successfully both before and after operation. Radium has its distinct limitations in the treatment of cancer, but, on the other hand, it has its rôle in the treatment of this disease which is of great importance. As a therapeutic agent for many other diseases radium is of decided value and moreover the medical profession has yet much to learn concerning its merits.

THE OUTLOOK FOR VACCINATION IN GREAT BRITAIN.

THE principle of vaccination as a protective measure against smallpox was discovered in England, and yet of all the civilized countries of the world it is in England that the greatest amount of opposition to the carrying out of the operation is manifested. If the National Insurance Bill passes general vaccination in Great Britain is doomed. In the House of Commons a few weeks ago Mr. Lloyd George proposed to accept an amendment to the bill to the effect that no insured person shall be subject to any penalty, whether by suspension of benefit or otherwise, on account of the refusal by any such person to submit to a surgical operation, or to vaccination or inoculation of any kind. A member of Parliament asked whether it was not lawful to save a man's life against his will, and Mr. Lloyd George answered, "You ought not to deprive a man of benefit because he has come to the conclusion that he will not risk his life in an operation." The member of Parliament might have asked, Is it lawful to risk the health of the community at large because an ignorant person is unwilling to undergo a treatment which has been conclusively proved to prevent the spread and to temper the virulence of one of the most terrible and infectious diseases known. It would be a mere

waste of time to recapitulate the evidence in favor of vaccination. The wonderful results brought about by its enforcement in Porto Rico and the Philippine Islands should suffice to convince every doubter. It seems, however, to be an instance of whom the gods will destroy they first make mad.

Sunlight in the After-Treatment of Cancer.

Remedies designed to retard the return of cancer have been sufficiently numerous in the past. We need only mention two, viz., the seton and arsenic internally, both of which were believed to act upon the organism at large, and not merely on the region of the extirpated cancer. It is evident that we must have some biological test of the organism at large in respect to the recurrence of cancer after radical extirpation, otherwise a patient seemingly well may have latent cancer. Such a test is believed by Professor Hochenegg, among others, to exist in the so-called Freund reaction. According to the latter the serum of non-cancerous subjects dissolves cancer cells. At a recent meeting of the K. K. Gesellschaft für Aerzte (*Münchener medizinische Wochenschrift,* July 18) Professor Hochenegg, so well known for his work on rectal cancer, said that he believed, on the strength of a negative Freund reaction, that a rectal cancer had been practically prevented from recurring by a vigorous sun bath and light treatment. The interval is but fifteen months, but the force of the claim is realized when we read that up to eleven months after operation the reaction was positive. If the test is a valid one the solar rays appear actually to have changed the patient's constitution as far as a disposition to cancer goes.

News of the Week.

Vital Statistics.—The monthly bulletin of the State Department of Health for the month of July shows that the total number of deaths from all causes was decreased by 438 from the number for the corresponding month of last year. The number of deaths of infants under one year of age was 2,590 as compared with 3,486 for July, 1910. The number of deaths from pulmonary tuberculosis was 1,101, of which 650 died in Greater New York. There were 486 cases with 94 deaths of typhoid fever reported in July, 1910, while during the present year there were 641 cases with 125 deaths. The increase was about equally distributed between the urban and rural population.

The Cholera.—Official advices from Italy state that the city of Gio del Colle has been the scene of savage excesses in consequence of the cholera epidemic. A frenzied mob broke into the hospital and carried away those suffering from cholera and freed the suspects. It became necessary to call out soldiers, carbineers and even sailors to quell the riot. Similar scenes were enacted in the town of Massafra. In Turkey soldiers suffering from the disease were thrown from a military train and allowed to die on the ground. The disease continues to spread among the troups from Albania. Several suspicious cases have occurred in Vienna and twelve cases in a Servian town near Belgrade. Since the beginning of the present year the total number of deaths from cholera in Italy has been more than 30,000.

Unusual Rush for Vaccinations.—The week ending September 9 was one of the busiest in the history of the New York Health Department. During the week nearly 5,000 children were vaccinated at the offices of the department, the record for one day being 1,900. In addition to the demand for vaccinations caused by the approaching opening of the schools there was a rush for birth certificates. To prevent such a condition in the future a card-mailing system will be introduced for applications for birth certificates.

Sanitary Work in Charleston.—The Health Department of Charleston has been doing admirable work since the hurricane disaster. The citizens have been instructed as to the best methods to use and their cooperation with the department has been secured. To those who are unable to pay, the city furnished lime and other disinfecting materials. It is believed that the effective work of the health department will avert disease which so often follows in the wake of disasters like that which recently occurred in Charleston.

Saccharine Barred Out.—The New York Board of Health has added an amendment to its Sanitary Code forbidding the use of saccharine in foodstuffs and beverages. This action of the Health Department is in line with that of the division of food inspection of the Department of Agriculture which forbids the use of saccharine in the District of Columbia after January 1.

Medical Testimony and the Criminal Insane.—At the meeting of the American Institute of Criminal Law and Criminology in Boston on September 1, a report dealing with the testimony of expert witnesses in criminal cases where insanity is the plea of the defense was presented by a committee of physicians and lawyers who have been investigating this subject. While the report of the committee was not final it made the following recommendations: That legal tests of insanity be abolished; that insanity should be held to be a good defence whenever it negatives the necessary criminal intent: that various medical associations shall establish and maintain a code of professional ethics to govern medical reports; that the various bar associations shall establish a code of professional ethics to govern counsel in criminal trials where the defense of insanity is raised; that medical witnesses who give opinion evidence in criminal cases, where the defense is insanity, shall be chosen from a qualified group.

Contribution to Freeport Hospital.—Dr. W. W. Krape, founder of the Globe Hospital of Freeport, Ill., has given this institution an additional gift of $6,500 for an addition and improvements needed by the hospital.

A Hospital for Pellagra.—Atlanta, Ga., is to have the distinction of establishing the first hospital in the world entirely devoted to the care of patients suffering from pellagra. This institution, which is an annex to the Tabernacle Infirmary, will be opened on September 11, and offers accommodations for twenty-one patients.

Buys Site for Tuberculosis Sanatorium.—The State Antituberculosis Commission of Texas has purchased a tract of 375 acres of land in the North Concho Valley near San Angelo, upon which tuberculosis colony buildings are to be erected in the near future.

Infants' Hospital Ends Season.—Junior Sea Breeze Hospital, an emergency hospital at Sixty-fourth street and East River, maintained by John D. Rockefeller, has closed for the season. There

were 173 sick babies cared for in the hospital and 361 in the dispensary. The mortality this year was only 29 per cent., while for 1910 it was 38 per cent.

Association of Life Insurance Medical Directors of America.—The twenty-second annual meeting of this Association will be held in New York City on Wednesday and Thursday, October 4 and 5, in the Board Room of The Mutual Life Building, 34 Nassau Street. The following papers will be read: "A Suggested Readjustment of Our Views on Heart Examinations for Life Insurance," by Chas. F. Martin, M.D., Medical Director of The Standard Life Insurance Co. of Montreal, Canada. "Alcohol and Life Insurance," by T. F. McMahon, M.D., Assistant Medical Referee The Manufacturers' Life Association Company, Toronto, Ont. "The Use of the Sphygmomanometer in Life Insurance Examinations," by John W. Fisher, M.D., Medical Director The Northwestern Life Insurance Company, Milwaukee, Wis. "Some Observations on the Means of Detecting Adverse Selections," by Arthur B. Wood, Actuary Sun Life Assurance Company, Montreal, Canada.

The Eastern Medical Society.—A meeting of this society will be held in the Academy of Medicine on September 20. The scientific feature will be a symposium on "Practical Features of Ear Disease," in which papers will be read by Drs. S. MacCuen Smith of Philadelphia, George L. Richards of Fall River, E. A. Crockett of Boston, and Albert A. Gray of Glasgow, Scotland, a guest of the society. A general invitation is extended to the medical profession of the city.

New York State Homeopathic Society will hold its forty-fifth annual meeting from October 10 to 14, inclusive, at the Flower Hospital, New York City. Dr. Orlando S. Ritch of Brooklyn is President, and Dr. Bert B. Clark of No. 6 West 129th St., New York City, is Secretary. The headquarters of the society will be at the Hotel Savoy.

Dr. Charles A. Mohr has been elected Health Officer of the City of Mobile, Ala., to succeed Dr. Rhett Goode who recently resigned after having served for twenty years.

Dr. Wiley.—The Homeopathic Medical Society of Pennsylvania at its recent meeting at Bedford Springs adopted a resolution to the effect that "the removal of Dr. Harvey W. Wiley from his position as chief chemist of the United States Department of Agriculture would be a calamity to the nation and a direct blow to the health of every citizen."

Award of the Cameron Prize.—The University of Edinburgh has awarded the Cameron prize in practical therapeutics to Dr. Simon Flexner of New York, who is director of the laboratories of the Rockefeller Institute for Medical Research. This prize, which amounts to $500, is awarded every five years to a person who has made an important contribution to medical therapeutics. Dr. Flexner has received this prize in recognition of his researches on epidemic cerebrospinal meningitis and its treatment with antimeningitis serum. Dr. Flexner has been invited to deliver an address at the University of Edinburgh during the coming academic year on the researches in recognition of which he has received the prize.

Dr. Theodore C. Janeway has been elected a member of the board of scientific directors of the Rockefeller Institute of Medical Research to fill the vacancy caused by the death of Dr. Christian A. Herter.

Obituary Notes.—Dr. Benjamin Edson of Brooklyn, N. Y., a graduate of the New York University in 1873, member of the Medical Society of the State of New York, King's County Medical Society, Brooklyn Pediatric Society, physician for the Home for Destitute Children, died at his home September 5, aged 70.

Dr. George Alexander DeSantos Saxe died of heart disease on September 10 at his home in this city. He was born in St. Petersburg, Russia, February 22, 1876, and was educated at St. Peter's College in St. Petersburg, then at Columbia University Medical College in New York, where he was graduated with honors in 1898. He was at different times pathologist at the Columbus Hospital, assistant genitourinary surgeon at the Post-Graduate Hospital, as well as instructor there. He was a member of the Medical Society of the County of New York and of the State of New York, of the New York Academy of Medicine, of the American Medical Association, the American Urological Association, the National Association for the Prevention of Tuberculosis, the American Medical Editors Association, and the American Society of Social and Moral Prophylaxis. He was joint editor of "Blackboard Headings on Surgery," author of "Examinations of the Urine," and assistant editor of the *New York Medical Journal*.

Dr. George F. Harris of Bellefont, Pa., a graduate of the University of Pennsylvania, Department of Medicine, in 1864, member of the American Medical Association, died at his home September 10, aged 68.

Dr. Wyatt P. Exum, Jr., of Saulston, N. C., a graduate of the Medical College of Virginia, Richmond, 1901, died at his home August 18, aged 78.

Dr. Walter Owen Tyan of Springfield, Ill., a graduate of Rush Medical College, Chicago, Ill., 1896, died in Los Angeles, Cal., September 1.

Dr. William B. Lane of Brooklyn, N. Y., a graduate of Bellevue Hospital Medical College in 1864, a director in the Manhattan Life Insurance Company and its Vice-President for many years, died at his home in Brooklyn, August 27, aged 74.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

SUMMER HEAT AND MORTALITY—CONSUMPTION DISPENSARY SYSTEM—PULMONARY ANTHRACOSIS—ACTION OF RADIUM ON SOUND TISSUES—ANTHRAX REPORT—OBITUARY.

London, August 25, 1911.

The most delightful summer that England has experienced for many a long year has broken up, and we find ourselves in autumn weather, ushered in by two or three thunderstorms. Many people complained of the heat and declared its continuance was abnormal, but already they are speaking almost with regret at its conclusion. A heat wave seems to have passed all over Europe, but according to the accounts it was not to be compared with what you in New York sometimes experience. In this island it was milder than on the Continent, but still unusual. Temperatures above the nineties have been often recorded this summer. The eighties are not very common in our climate, but all over England we have had readings of 90 to 97, and one day at the Royal Observatory at Greenwich, 100 F., which I think is unprecedented. The shortage of rain was serious for the crops, and in a few places water was

scarce. The chief medical interest in these conditions lies in the mortality, which was increased, especially among children in closely inhabited localities. The weekly returns of the annual death rate in the great towns from all causes rose from 12.1 to 13.6 and 15.9 per 1,000. In London the returns were 11.4, 13.7, 15.5, 18.7, giving an average of 14.8, or 3.4 above the mean of the same period for the previous five years. The infantile mortality also showed progressive increase. In children under 2 the deaths from diarrhea and enteritis numbered in the successive weeks 56, 157, 318, 548. The Local Government Board issued a circular to sanitary authorities to impress on them the importance of taking special steps above those required in cold summers to minimize the excess.

The appeal on behalf of the Central Fund for the Promotion of the Dispensary System for Dealing with Consumption in London has been successful thus far. Some £40,000 has been subscribed and the committee hope the fund will reach £100,000 before the end of the year. Additional grants have been made to dispensaries actually in existence. Others are in course of examination; probably about nine will be at work in the coming winter. The committee have issued a list of the districts which in their opinion should be dealt with, based on the population, mortality from pulmonary tuberculosis in each, and the estimated approximative number of living consumptives in each. According to these figures it appears that about twenty dispensaries will be necessary to meet the requirements of the whole of London. It is expected that some will be adequately supported locally. Reckoning all together, they think one-quarter of the total cost may be the average contributed locally; the remaining three-fourths would have to be found by the fund. The cost of the Paddington dispensary for the first year was about £1,000, which sum may be taken as the probable average. Thus for the twenty dispensaries the three-fourths from the Central Fund would consume £15,000, but inasmuch as it is proposed to devote something for sending certain patients to sanatoria or to homes for the dying, as much as the one-fourth given locally would be needed in addition, so that £1,000 is really wanted for each dispensary established, and if the twenty estimated can be started, the fund will want £20,000 a year to keep them up.

Although the tuberculin treatment is at present in the ascendant it is as well, perhaps, that the promoters of the scheme have not so named their institutions, but are content to appeal for them as "consumption dispensaries," a name well enough understood by the public, and leaving every therapeutical principle open to the consideration of the staff. They will care for the patients on the most modern lines—open air, vaccine therapy, selection for sanatoria, hospitals, farm colonies, etc. Their work will not be confined to the applicant; they will follow him to his home, see and correct, if needed, his home conditions, examine the others of his household so that the earliest case may be detected. Thus they will endeavor to recreate healthy homes, well instructed as to prevention, and serving as bases of operations and intelligence in the campaign against consumption.

The system, if new in London, has been well tried in Edinburgh, where it was instituted in 1887, and has thence spread through many countries. The last report of the Registrar-General for Scotland shows that the death rate from consumption during the last decade has been less in Edinburgh than in any other center. The fall there in 1910 was 46.4 per cent. from 1901. During the same period in London the fall was approximately 30 per cent. only.

Mr. Percival Mills of Birmingham described in the Pathological Section of the last meeting his research on the action of radium on healthy tissues. He applied it to the liver of mice and produced two inflammatory reactions, one of which began immediately, affected all the tissues for three hours, and faded away in twenty-four hours. It caused a cloudy swelling with hyperemia lasting a week. The other "late reaction" began after fourteen days and lasted 113 days, when the last mouse died. Infiltration and hyperemia resulted, and finally some fibrosis. Professor Sims Woodhead said here was something which might be of some help to the production of cirrhosis. These illustrations suggested that the primary changes in cirrhosis were associated with the parenchymatous tissues and followed by interstitial changes.

Dr. Leonard Findlay related his experimental work on the origin of pulmonary anthracosis. These experiments are directly opposed to the views of Calmette and Whitla. In no case could he produce this lesion by injecting into the peritoneum, but in every experiment by inhaling he succeeded in doing so, provided, of course, the bronchi were patent. In animals killed after one short inhalation the pigment was found in the alveoli and bronchioles. When repeated inhalations had been given, besides finding more pigment in the alveoli, it was also found in the pulmonary tissue and bronchial glands. To many of us this is just what we anticipated, for in the post-mortem room we are familiar with the appearance of the lungs as pigmented, even in the autopsies of young children. Dr. Sims Woodhead expressed interest in the experiments and had no doubt as to the channel through which the pigment reached the lung, but of course that did not prove that bacilli took the same route. He had confirmed Dr. Findlay's results.

Professor F. C. Leith hoped Dr. Findlay's experiments would be accepted as re-establishing the old view that the pigment entered by the respiratory tract. It was not denied, however, that bacilli might differ from inorganic particles.

Dr. C. Pouder is a bacteriologist at the technical school of the Leathersellers Company, and has prepared a report issued by that worshipful company on the incidence of anthrax. In it he examines the various methods that have been proposed for meeting the danger among persons engaged in the hide, skin, and leather industries. After a full consideration he concludes that the best plan is to convert these materials into the "wet salted" condition propposed recently by Mr. Seymour Jones, chairman of the International Commission on the subject. The hides are first soaked for twenty-four hours in a solution of 1 per cent. of prussic acid and 0.02 per cent. of sublimate, and then transferred to a brine pot. This could easily be done at the port of shipment, and does not interfere with the subsequent process of conversion into leather. Nor does it injure the goods commercially.

Dr. John Dixon, who died suddenly on the 15th of August, was surgeon to the Mildmay Mission to Jews and to the French Protestant Hospital. He took L.R.C.P. (1870), M.B., and C.M., Edinburgh, 1872.

Surgeon Lieutenant-Colonel James Scanlan of the Army Medical Staff (retired) died on the 12th.

aged 64. He was M.B. and C.M., Glasgow, 1868.

Surgeon Lieutenant-Colonel E. R. O'Brien, Army Medical Staff, died on the 13th, aged 69. He was M.D., R.U.I., 1863, and a licentiate of the Edinburgh and Dublin Colleges of Surgeons.

Dr. L. H. Stevenson died on the 11th of August at the age of 63. He took the two college diplomas and the M.B. with honors of the London University in 1876-7, and in 1879 proceeded to the M.D.

Dr. G. Fielding Blandford, who has for many years been known as an eminent psychologist, died on the 18th inst. at the age of 82. He went to Rugby School and continued his education at St. George's Hospital and the Oxford University, where he graduated in both arts and medicine, M.A., 1854; M.B., 1857; M.D., 1867. He took the membership of the London College of Physicians in 1860, and was elected a fellow in 1869. His "Insanity and Its Treatment" passed through several editions. His Lumleian Lectures on this subject were issued in 1895. He wrote the article on Insanity in Quain's Dictionary and contributed on this and allied subjects to other medical publications. You will perhaps remember that he gave an address on the "Treatment of Insane Patients" at the International Medical Congress at Washington, 1887. He was lecturer on Psychological Medicine at St. George's Hospital, had been president of the Psychological Association, and was president of the Society for the Relief of Widows and Orphans of Medical Men.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

DEATH OF HERMANN SENATOR—PRACTICAL VALUE OF THE WASSERMANN REACTION.

BERLIN, August 15, 1911.

HERMANN SENATOR died July 14 at the age of 77. With his death there passed away one who to the thousands of German physicians who had been his pupils, had dedicated so much of his life work. We have certainly had more brilliant teachers, who with shining rhetoric were able to make each simple case of illness an important chapter in medical science. Nevertheless this was not always of practical value in the physician's daily work. All the more grateful are we to the man who, with utmost patience in the presence of every case of disease, transported his audience with his modest sense of reality and his exquisite conscientiousness. Moderation characterized his speech, but as clear as crystal and without a gap, thought followed thought until the speaker had exhausted all that science has as yet definitely contributed to the subject under discussion. A student who had attended one semester at Senator's clinic received a thorough grounding in clinical medicine. Only recently, when Senator left the position that he had held for so many years, the question of his successor has come up. His status with reference to medical life in Berlin was an extraordinary one. He was the last representative of the older school of general practice that has given place to the modern specialization of medical science. He was not responsible for any revolutionary discovery in medicine, but in every branch of this he had become a master.

When not yet 20 years old Senator came to Berlin and became a pupil of Johannes Müller, Schönlein, and Traube. Four years later he began the practice of medicine in a district inhabited by laborers. Here he laid the foundation of his subsequent success as a teacher, acquiring an experience of the daily needs and resources of the practitioner. In 1868 he became a privat dozent at the University. In the war of 1870 he commanded a hospital division and thereby came under the notice of the Empress Augusta. When in 1875 the Augusta Hospital was established, the Empress besought Senator to become director of the medical division, and through her influence Senator in 1881 received a division in the Charité, in which, in 1888, he became director of the policlinic.

Ever since 1868 Senator published a large series of articles, chiefly on fever, heat production, and metabolism. Beginning with 1874 there followed numerous contributions on diseases of the kidneys, which labors above all served to spread the fame of Senator, whose activity continued into ripe old age and grappled with the problems of to-day. His latest work, among other things, dealt with Banti's disease, internal secretions, and blood pressure. An exceptional phase of his industry was his devotion to the laboratory, where, with his many assistants, the scientific methods of the master became the property of an untold number of practitioners. The medical society of which Senator was president for many years will hold a memorial meeting October 25.

"The Practical Value of the Wassermann Reaction in the Treatment of Syphilis" was the title of a paper read by von Plehn before the Medical Society. Plehn doubts the practical utility of the reaction. He reaches this conclusion because the reaction is positive in many nonsyphilitic affectins, because it is sometimes positive and sometimes negative in the same individual, and finally, because the reaction is distinctly positive in many healthy people of advanced years. Now, since the negative reaction is no evidence that a case of syphilis is cured, and since under the most energetic treatment the reaction does not disappear, the reaction can not be regarded as an index of the treatment. In the first stage of syphilis treatment causes the reaction speedily to become negative, and it is therefore in this stage that the reaction is of great value. In the later stage of the disease caution must be exercised, particularly in nervous cases in which a syphilitic etiology is under consideration. In the numerous investigations that Plehn carried out, the question of error can be eliminated, for in every case controls were made with five extracts.

The Causes and Treatment of Paralytic Dislocations and Subluxations of the Hip-Joint. J. W. Sever.
Interstitial Gingivitis. E. C. Briggs.
Wound Diphtheria. Report of a Case. F. A. Thompson, Jr., and W. R. MacAusland.
Rupture of the Uterus Through the Posterior Vaginal Fornix. A. T. Hawes.

Paralytic Dislocations and Subluxations of the Hip-Joint.—J. W. Sever concludes that subluxations of the hip joint are not uncommon conditions following paralysis of the thigh and peritrochanteric muscles. The most important factors in their production are the unopposed contractions of the non-paralyzed muscles. The two muscles which escape the paralysis most frequently are the adductors and the tensor vaginæ femoris. The most common type of subluxation is upward and backward on to the ilium. The changes from atrophy in the femur and acetabulum are practically constant, and consist of a

coxa valga and a shallow, flattened, and elongated acetabulum. The treatment should be directed toward correcting the contractions and reducing the dislocation of the hip. The muscles may be elongated by stretching, by means of plaster casts, bed traction, or division. The best method of keeping the hip reduced is by means of an arthrodesis, although this is not practical in all cases. Without treatment the tendency is toward progressive deformity. With treatment the conditions may be permanently helped. Complicating conditions make a total cure impossible, but a more useful leg should be assured under proper treatment. Walking after arthrodesis is often improved. In some cases splints may be altogether discarded. It is not advisable to do an arthrodesis on both hips, or on any joint other than the hip and ankle on the same leg.

Interstitial Gingivitis.—E. C Briggs states that the flow of pus as a symptom of this condition comes late in the disease, and after the deposition of the nodules. He assumes that intestinal putrefaction is the primary cause of gingivitis, by disturbing the circulation and rendering the connective tissue of the gum an easy prey to vitiating influences. Some of the local conditions that may be the starting point of inflammations are malposition of the teeth, the deposition of salivary calculus, impacted teeth, and improper toothbrushes and their improper use. Interstitial gingivitis first announces itself by a feeling of uneasiness of the gum, a sensation described as a "crawling," or by a sensation of pain with some lameness of tooth or teeth. The early symptoms may even simulate alveolar abscess. There is sometimes in the mildest forms of the disease a considerable recession of the gum. In the severe forms there is generally pus formation. Preventive treatment consists in careful hygiene of the mouth, the correction of malocclusion, the maintenance of the thorough use of the teeth in mastication, and the prevention of intestinal antointoxication. The first step in the curative treatment is attention to the gastrointestinal tract. For the gingivitis aspirin and calcium sulphide are good remedies. The local treatment consists in thoroughly scaling the affected teeth, in removing diseased pulp, and in stimulating the diseased pockets.

Wound Diphtheria.—F. A. Thompson and W. R. MacAusland describe a case of diphtheritic infection of the skin following a compound fracture of the patella. They note that diphtheria infection of a wound is much more difficult to check than other infections; that the local treatment plays an important part in limiting extension and destruction of tissue; that antitoxin plays a double rôle in attacking the local manifestion of the process, as well as defending other parts by neutralizing the toxins in the blood stream.

Rupture of Uterus.—A. T. Hawes reports a case of rupture of the uterus, in which the rent extended transversely across the vaginal vault in the posterior fornix. The patient recovered.

Tendencies Toward Race Degeneracy. J. H. Kellogg.
A Series of Studies of Nervous Affections in Relation to the Adjustments of the Eyes. G. T. Stevens.
The Location of Pathological Lesions of the Genitourinary Tract from Epithelia Found in Urine. G. A. Wyeth.
Cerebral Rheumatism. E. M. Williams.
Suicide in the Registration Area. H. A. Brown.
Triple Rhythm Heart Block with Auricular Interruption. A. L. Benedict.
Suction Drainage with a New Form of Siphon Air Pump, as a Means of Removing Pus and Blood from the Abdomen and Pelvis. N. G. Bozeman.
Some Interesting Data on Recently Reported Research Work on Dysentery. S. R. Klein.

Race Degeneracy.—J. H. Kellogg states that man belongs to the most highly organized class of mammals, a group which paleontology shows to be the most prone to degenerate. In addition to this, civilized man has, in recent times, subjected himself to a number of subtle degenerative influences. There is at the present time a decided tendency toward physical decay and race degeneracy among civilized nations. Evidences of race degeneration are manifest in the diminishing stature; the tendency toward an edentulous condition; the alarming decrease in the birthrate; the increasing number of incompetent mothers; the appalling increase of insanity, idiocy, and imbecility; the rapid spread of cancer; the increase of eye and ear defects; the doubling of mortality from chronic disease within the past thirty years; the notable increase of crime; the decrease in the number of centenarians; the anatomical evidence of degeneracy in man; and the new and abnormal varieties of the human race, such as the criminal type, the insane type, etc.

Eye Adjustments and Pose of the Body.—G. T. Stevens advances the proposition that, depending upon certain conditions of adjustment of the eyes, there result certain well defined habitual positions for the carriage of the head and that these habitual carriages of the head in relation to the body induce certain well defined positions of the body itself. Further, these bodily positions are, in many cases, indeed in many special forms of disease, the inducing and perpetuating causes of not only certain nervous affections but of certain important diseases not classed as nervous.

Diagnostic Value of Urinary Epithelia.—G. A. Wyeth reports a series of cases which illustrate the results obtained from careful microscopical uranalysis, since the diagnoses were corroborated by operation. The author states that others could be cited in which a doubtful clinical diagnosis was entirely cleared up by the microscopical findings in the urine. Such cases prove beyond a doubt that, through the differentiation of the various epithelia in the urine, one has a reliable means of locating lesions in the genitourinary tract, regardless of whether the pathological condition can be diagnosticated or not. Of special value is the work in the early recognition of inflammatory conditions of the kidney, as many cases of nephritis exist without the presence of casts.

Cerebral Rheumatism.—E. M. Williams reports four cases of this condition with pathological findings. The interesting features of the latter, in addition to the meningeal and cellular changes already described by other observers, are the presence of numerous cells similar in every respect to the so-called plasma cells, numbers of fatty granular cells, and also an abundance of globular, pale blue staining bodies, probably of albuminous nature, having their origin from the disintegrated tissue. The great intensity as well as the diffuseness of the cellular changes is exceptional, as are also the vast extent and degree of the neuronophagocytosis.

Suicide.—By H. A. Brown. (See page 590.)

Triple Rhythm Heart Block.—A. L. Benedict reports a case in which the arterial pulse was fairly strong and regular, twenty-five a minute. The jugular pulse was three times as frequent and in perfect triple time, but careful inspection of the neck showed that the auricular beat immediately preceding the ventricular was imaginary, or, at most, so faint as to be imperceptible, although the perfection and steadiness of the rhythm at first gave the impression that one had to deal with a three to one ratio of auricular to ventricular contractions. The author states that with a very slowly acting ventricle and a firm closure of the auriculoventricular valve it is conceivable that a double wave might occur in the blood in the auricle and great veins, without any secondary contraction of the auricle.

Section on Ophthalmology.—A. E. Bulson in discussing the welfare of this section of the American Medical Association, states among other things that the Knapp Testimonial Fund has been established and that it has been decided to procure a medal, to be known as the Knapp Medal of the Section on Ophthalmology, and offer the same to invited as well as uninvited contributors to the Section on Ophthalmology for original work in ophthalmology, or for some contribution of such a highly meritorious character in the field of ophthalmology as will warrant the granting of a medal as a special recognition.

Chancres from Kissing.—J. F. Schamberg describes the following epidemic: At a party of young people at which juvenile kissing games were indulged in, one of the participants, a young man of 22, had a sore on his lip, the nature of which he avers he did not know. Six young women kissed by him developed chancres of the lip. A young man present at the affair likewise developed a chancre of the lip apparently from the virus deposited on the lips of one of the young women, for he did not come into contact with the original source. In addition, a young woman kissed by the offender at a third social function likewise developed an initial sclerosis, making in all eight labial chancres from the one source. The original offender was apprehended, taken to the municipal hospital, and given an intravenous injection of salvarsan. But he was not isolated.

Aberrant Thyroids.—By C. H. Mayo.—See MEDICAL RECORD, July 8, 1911, page 100.

Treatment of Scoliosis.—R. W. Lovett and J. W. Sever refer to two varieties of lateral curvature, the postural and the organic. The former is nothing but a faulty attitude or habit which is often overlooked. There is no tendency to its spontaneous recovery, but the treatment is simple. The general hygiene should be looked into, overwork at school and home prevented, and, if the child is of low resistance, lying down a while during the day is advised. The weight of clothing should not drag on the shoulders, round garters should be substituted for side elastics, and clothes suspended from the waist should be as light as possible. Any visual errors causing improper positions in reading should be corrected and measurement of the legs should be made to see if an improved position of the spine results from equalizing the limbs. Then exercises and a setting up drill should be carried out under good supervision. The daily active treatment generally covers a period of not more than three or four weeks, but the observation period should last at least a year. The organic lateral curvature is accompanied by changes in the vertebræ and may occur from various causes in infancy, such as congenital anomalies, infantile paralysis, empyema, and conditions approaching rickets. Gymnastics as a treatment is generally condemned by the author, excepting in very slight cases and only as long as it shows good effects. The permanent jacket is better suited to hospital practice, while the removable jackets are more acceptable to private patients and, where the patient is under complete control, are nearly as efficient as the other, though requiring perhaps a longer period of use.

Hookworm Disease in Children.—T. Frazer notes that mild cases of hookworm disease may be easily overlooked. He reports a number of these cases in children who after a course of thymol showed rapid gain in weight and strength and increase in intelligence.

A New Proctoscope and Sigmoidoscope.—D. Roberts has devised an instrument one feature of which is a flat-faced metal filament lamp snugly held in a tube which projects at an angle of 30 deg. from the main tube, the inside of which is heavily plated and highly polished with lines of polish running lengthwise. Owing to the manner of polishing, no light is thrown back into the eye from the walls of the tube, all the rays going to the distal end. The end of the obturator is much less blunt than in the previously made instruments, as bluntness is not needed for safety.

Cardiac Displacement.—E. O'N. Kane reports a case of extreme displacement of the heart to the right side resulting from a left-sided empyema.

Elicitation of the Knee-Jerk.—A. A. Eshner describes two procedures which he has found useful in eliciting a dubious knee-jerk. The first consists in supporting the leg to be examined on an inclined plane while the patient is seated, the slope of the plane being varied to suit the needs of the case. This secures relaxation of the limb independently of the volition of the patient and the limb can be placed in the most favorable position for bringing out the symptoms. It is particularly useful in case of obese individuals and in case of patients who will not willingly cooperate with the examiner. The second procedure consists in the application of the palmar surface of the index finger of one hand over the patellar tendon and striking the dorsal surface of this finger with the percussion hammer or with the opposite clenched hand. In this way a slight contraction of the tendon can sometimes be felt though not otherwise demonstrable.

Frontal Sinus and Ethmoid Labyrinth.—H. Horn states that, having determined that an external operation on the frontal sinus and ethmoid labyrinth is necessary, there is not any question but that the mutilating radical operation of Riedel, with its complete destruction of the supraorbital ridge, is the one that gives the greatest certainty of a cure.

Frontal Sinus Disease.—B. R. Shurly states that the most frequent pathological condition is the ascending infection from a common cold in the head. The most frequent invaders are the staphylococci and streptococci, the *B. pyocyaneus* and the pneumonia and influenza germs. The inflammations in bony cavities are much like inflammations elsewhere, but the necesssity for prompt attention and drainage is more important. The inflammation is sometimes very rapid and destructive and special pathological conditions may develop. The influence of the biochemistry of the blood and lymph and the general systemic condition should also be kept in mind. A routine bacteriological examination should be the rule. Cysts and polypi are frequently formed in the other accessory sinuses and suppuration may be free or scanty, according to the freedom of drainage, and fistulæ may occur in rather rare instances. Among the most frequent infectious conditions are influenza, tuberculosis, and syphilis.

Tubercle Bacilli and Epithelium.—S. G. Dixon, A. J. Smith, and H. Fox state that the results of their experi-

ments in stimulating superficial epithelium were not very positive. They conclude that a combination of living tubercle bacilli and tuberculin is necessary for this purpose.

Pathological Physiology of Thyroid Disease.—By J. Rogers. See MEDICAL RECORD, July 8, 1911, page 102.

Goiter Operations.—By M. B. Tinker. See MEDICAL RECORD, July 8, 1911, page 102.

The Phenolsulphonephthalein Test.—B. J. T. Gerachty and L. G. Rowntree. See MEDICAL RECORD, Vol. 79, page 1,028.

Alum Baking Powder.—W. J. Gies concludes that, unless it can be shown definitely and beyond a reasonable doubt that aluminized foods are harmless, the use in food of such aluminum carriers as alum baking powders should be prohibited by law in the interest of public health.

Ureteral Anastomosis.—J. J. Gilbride describes experimental work performed on the cadaver and on dogs in anastomosing the proximal end of a divided ureter into the side of the ureter of the other side.

Potassium Chlorate Poisoning.—M. M. Scheid reports a case of this condition in a twenty-day-old baby caused by the administration of "borrowed medicine."

Rupture of Rectus Muscle.—M. A. Stern reports a case of rupture of the left rectus resulting from a blow in the abdomen by a heavy truck.

British Medical Journal.

Spa Treatment, with Special Reference to Moffat. D. Huskie.
Tuberculin Dispensaries: A Reply. W. C. Wilkinson.
The Frenkel System of Exercises for Tabes. J. G. Garson.

Spa Treatment.—D. Huskie notes the mention of mineral springs as far back as the early biblical era. Hippocrates demonstrated the curative effects of waters apart from the supposed power of the presiding deity or spirit. Rome left abundant proof of the balneological practices of her people. The amount of "drug" potential in the molecular states of a mineral water is very small, and yet it has a vastly greater effect in certain affections than an enormous amount of the artificial salt. Spa treatment is concerned largely with chronic conditions and intractable constitutional states. The sulphur water of the town of Moffat has a marked diuretic effect. It also increases oxidation and tissue change. The action of the warm sulphur baths seems to be due to a nervous and vascular cutaneous reaction attributable to the irritation of the contained salts, modified to a certain extent by the temperature of the water.

Tuberculin Dispensaries.—W. C. Wilkinson believes that sanatorium treatment with its system of graduated exercises is no real help to the consumptive poor. Moeller of the Belzig sanatorium near Berlin states that sanatorium methods by themselves cure only 10.0 per cent. of the cases and 25.3 per cent. of the incipient cases, while tuberculin has cured 84.6 per cent. of the latter. The author is convinced that in the first stage of the disease tuberculin cures pulmonary tuberculosis with certainty, and that in the second stage of the disease the routine use of tuberculin is the best means of preventing mixed infections. By the system of graduated doses which can be measured with mathematical accuracy there is not the same need for constant medical supervision as is customary in sanatoria. The patients are taught to take their own temperatures. The expense of the tuberculin treatment as carried out in dispensaries is $10 as against $150 for each patient, which makes the former treatment one better adapted for the poor. Under tuberculin treatment cough and expectoration subside and the patients cease to be a danger to their friends and relatives.

Frenkel Exercises in Tabes.—J. G. Garson states that, as long as a certain amount of sensibility exists in the muscles and joints, systematically performed movements, frequently repeated with the attention concentrated on the acts, produce certain impressions on the neurones still unaffected by the disease; these impressions are accumulated until their collective intensity equals that of a stronger but less frequent stimulus, and are capable of being reproduced by the central nervous system. The greater the loss of sensation the more difficult and prolonged will the treatment be, but in Frenkel's practice it has been rare to find a case in which the sensibility of the muscles and joints has been so reduced as not to be capable of great improvement. The exercises designed to be performed in bed or on a couch are done by patients separately, but the walking exercises are best done when three or four patients are simultaneously on the track and practise them alternately, as there is then a spirit of emulation and intentness of purpose aroused which has a very beneficial influence on the result.

Berliner klinische Wochenschrift.

August 21, 1911.

Melanoblastomata.—Kreibich has shown by the demonstration of a lipoid component in the pigment of so-called melanomata, melanosarcomata, etc., that these growths are derived not, as taught heretofore, from the mesodermal chromatophores, but from the epithelial pigment cells. The lipoid component, as demonstrated by special staining, is present also in the metastases. The epithelial cells which generate the pigment are termed melanoblasts and the tumors formed are therefore melanoblastomata. On account of this common property of forming pigment containing lipoid material, the author can see no radical difference between melanotic cancer and melanotic sarcoma. If spindle-cell elements predominate we have a melanotic spindle-cell sarcoma; if the elements are epithelioid we have a so-called pigmental alveolar cancer. Mixed forms are known to occur.

Chemotherapy of Pneumococcus Infection.—Morgenroth and Levy believe that bacteria are in reality as amenable to a therapia sterilisans magna as are certain kinds of protozoa. The power of quinine over the latter is well known, and this drug has been used extensively in large doses in various bacteriogenic diseases, especially in pneumonia. We have here the germ of an idea of finding in quinine derivatives remedies which will disinfect the organism of certain bacteria. The authors have satisfied themselves that quinine itself is not in the slightest degree bacteriotropic toward the pneumococcus. A quinine derivative known as ethylhydrocuprein having shown itself—along with other derivatives—to be similarly inert, it was finally ascertained that the sulphate salt of this body possessed undoubted prophylactic and curative influence over laboratory pneumococcus infection in mice. This compound is by no means looked upon as anything more than a step in the right direction. A further study of quinine derivatives may lead to the discovery of a drug having power over croupous pneumonia in man. Such a remedy would doubtless be used in connection with an antitoxin for it has been shown satisfactorily that antibodies are responsible for the cure of pneumonia by crisis. These quinine derivatives should also possess a field in streptococcic infections.

Rectal Infusion of Sugar Solutions in Diabetic Acidosis.—Balini calls attention to the fact that this resource is by no means new. Since acidosis is usually held to indicate that the point of carbohydrate tolerance has been passed, any such plan of treatment would be condemned *a priori*, and this assumption would be borne out were sugar given in the usual way. By rectal infusion, however, some new element must be introduced, for the sugar then seems to be properly utilized and the glycosuria is seldom increased. The utilization of the sugar spares

the proteid of the muscles, etc., and in some cases the acetone in the urine is notably cut down. As is well known, it is very difficult to get the rectum to retain solutions of glucose, as intolerance soon develops. The introduction must be in small quantities, frequently exhibited, and even with good tolerance much of the glucose remains unabsorbed. Still with patience the number of calories which can sometimes be supplied daily is very considerable. By the mouth the patient takes bouillon, a little cheese, etc. The entire technique is complicated, as in all similar plans for treating severe diabetes, feeding days alternating with fasting days, and the diet being regulated largely from the uroscopic findings.

Münchener medizinische Wochenschrift.

August 22, 1911.

Encephalitis Hemorrhagica Following an Infusion of Salvarsan.—Fisher comments on the surprising tolerance of the organism to intravenous injections of salvarsan, but insists that there must be individual examples of intolerance which must always be borne in mind. It may be recalled that some of the worst recorded cases of iodism were traced apparently to organic disease of the kidneys which was responsible for a highly toxic cumulative effect of the drug in subjects already suffering from syphilis. Something of this sort must be anticipated whenever the emunctories or disintoxicating organs are insufficient for the added demands made upon them. This element divides with anaphylaxis the responsibility for therapeutic tragedies. The patient in question was himself a medical man accidentally infected with syphilis, for which he had been duly mercurialized and had also received iodides. Salvarsan was then infused and although the Wassermann reaction had now become negative the patient became very ill at night after his usual daily routine. The symptoms suggested severe intracranial mischief and death occurred in coma in a little over twenty-four hours from the onset of the attack. The case is summed up as follows: It is known that between two and three days after an infusion of salvarsan an acute edema of the encephalon may develop, but that this quickly resolves itself and only exceptionally does a fatal encephalitis develop. Since this phenomenon has been noted chiefly after repeated injections there may be an anaphylactic element concerned (the patient had had a previous injection). Precisely the same accident has been known to follow mercurial injections in syphilitics, and it is believed that the action of syphilitic toxins on the encephalon is a contributory cause in such cases. When the patient first suffered from his general explosion of syphilis the cerebral symptoms were prominent. Finally the autopsy disclosed a beginning cirrhosis of the liver. The lessons from the case are in part obvious.

Encephalitis Hemorrhagica After Infusion of Salvarsan.—Almquist has had his first death after 184 cases of intravenous salvarsan treatment. The victim was a man aged 32 and autopsy showed no evidence of arsenical poisoning, despite the considerable amount of the drug infused. The patient was probably an alcoholic and had suffered from insomnia; these may have made his brain an organ of minimum resistance. The nature of the fatality, while obscure, must be set down to the drug, for several cases on record show that it can cause serious intracranial disturbance as part of the systemic reaction.

Salvarsan Infusion Without Reaction.—Herbsmann believes that systematic reaction after salvarsan infusion is practically constant. He regards a chill, headache, nausea, etc., as typical. Numerous other symptoms occur very rarely—as fever. These may be regarded as more or less accidental. A reaction should be expected as a guarantee that the remedy is not inert. As such it is welcomed by the patients themselves. Any attempts, therefore, to do away with the typical reaction by improvements in technique are a waste of time. The prevention of preventable accidents is quite a different proposition.

Deutsche medizinische Wochenschrift.

August 24, 1911.

Pathogenesis of Chronic Polyserositis.—Fogarasi writes of that paradoxical affection which has assumed so many clinical forms and has been "discovered" on so many different occasions. He chooses to call it by one of its older designations—Pick's pericardiac pseudocirrhosis—although he gives a good résumé of the views of other authorities, only failing to mention Bamberger, who is generally held to have been the true pioneer observer of the affection. The question of greatest significance seems always to have been the relationship of the perihepatitis to the obliteration pericarditis—largely because these two lesions often represent the sole clinical finds. It is not unlikely that the latter may have a dual nature. First it may represent the sole manifestation of a mysterious malady of unknown cause and nature, and, second, it may be a purely mechanical problem in which organic disease in a given organ causes organic changes in a neighboring organ. Thus a healthy subject contracts a pericarditis which ends in obliteration of the sac and resulting dilatation of the heart, which leads in turn to enlarged liver, hydroperitoneum, etc. Such a sequence, simple as it is, is by no means easy to distinguish from Pick's pericardiac pseudocirrhosis. An autopsy may show in a doubtful clinical case that the liver *per se* is practically intact and that what was looked upon in life as a stasis of that organ was in reality a thickened and inflamed condition of the hepatic capsule. Again, the deformity of the pericardium may be too slight to prejudice the integrity of the heart.

Oriental Boil.—This affection is now fairly well covered in textbooks, but Reinhardt of Constantinople finds our knowledge of it to increase so rapidly that the subject is in some need of revision. The lesions vary greatly from fixed types and often require differentation from other dermatoses. It is true that we now know its cause and nature, and that the treatment need not much concern us since the affection is self-limited. Aside from the confusion it may give rise to in the mind of the diagnostician it may lead to numerous complications, but these are such as may be found in any wound surface. Since the lesions occur practically everywhere on the surface, and while usually isolated may be confluent, they are readily mistaken for syphilis and tuberculosis. Occurring on the penis a so-called boil could hardly fail to simulate a chancre. Other affections simulated are ecthyma, furuncle, acne, and epithelioma. The disease attacks animals and is doubtless propagated chiefly through gnats and other insects. The specific protozoon which is known to cause the disease has been fully investigated in every way and few parasites are better known and understood. It seems hardly conceivable that only a few years ago the so-called "Aleppo evil," "Biskra bouton," "oriental boil," etc., was commonly assumed to be a form of syphilis or yaws, despite the fact that a more strictly local disease can hardly be imagined. It does not even infect its proper lymphatics and it does not appear to form any toxic products.

Koplik's Spots.—Mme. de Biehler finds that in measles these spots *always* precede the rash and are absolutely characteristic of measles. In 946 cases the spots appeared in 864 cases one day, in forty-two cases, two days; in eighteen cases, three days, and in 12 cases four days before the rash. Search for Koplik's spots is important in all acute diseases of infants, particularly for its prophylactic value.

Insurance Medicine.

The Relation of Physicians to Life Insurance.—Ex-Governor W. D. Jelks, president of the Protective Life Insurance Co., Birmingham, Ala., read before the Medical Association of the State of Alabama, at Montgomery, on April 18, 1911, a paper dealing with the relation of physicians to life insurance. After referring to the methods of insurance of bygone days it was pointed out that life insurance premiums now must be made with mortality tables in front of the actuary: the rates and tables keep step together. But it is only within recent years that these tables have been procurable. In the earlier times there was no experience table of mortality, and if there had been such a table the premium rate that is now known would have been impossible; indeed, genuine life insurance would not have been possible. We have tables now, however, on which to base all premium rates—an actuary to figure the exact cost of insurance. The business of insurance is tremendous. In 1909 176 legal reserve life companies in the United States had assets of $3.643.857,971. The premium rates of life insurance have been made in the face of mortality tables. It remains for the company to obtain not less than a fair average of physical risks; hence the importance of the medical examiners. Their selection is a matter of most serious consideration, as a company cannot afford to carry too many life discards. An examiner with a moderate degree of skill and efficiency in his line, and honestly serving the company, can give it a class higher than the average life. Such an examiner would recognize that the company was his client and entitled to the same fair dealing that he gives to the afflicted. He would appreciate the fact that his duty was to the company which appointed him and which was to pay him, and in no sense was he under obligation either to the agent who sold the insurance or to the candidate for insurance. Jelks said that the company of which he was an officer had no great number of complaints to make of the treatment which had been accorded to it by the various members of the profession in Alabama. However, their experience had not been altogether satisfactory. They had discovered that from some doctors there was reported a too great uniformity of pulse beats. Out of half a dozen cases from one physician the pulse of each applicant for insurance would be at the same rate as all the others. His pulse would beat exactly in time with the pulse of the several persons making application in the same community and in the same few days. These pulses not only seemed to stand up together, but to sit down together, and as a layman Jelks thought he had the right to say that pulses ought not to act in that way. Then occasionally was found a doctor suffering from the use of a urinometer on crutches. These items represented some of the more common complaints. Sometimes such examinations were refused. The medical department understood, of course, that the doctor was merely guessing at the specific gravity and pulse, if not sinning against the company in a more serious manner. It frequently happened in cases of this description that the company not only dismissed the doctor from its employ but the speaker understood that some companies uniformly filed a complaint against such a doctor with some central authority. When an occurrence of this nature took place the careless examiner found himself without a client in all the insurance world. Jelks believed he was conservative in saying that a good number of practising physicians had by their carelessness destroyed in a day their field of usefulness with all life companies. The companies felt that, inasmuch as they had been appointed to guard the door against wrecks and weaklings, if they failed it was very necessary to appoint some other guardian. The remainder of the paper treated of the life insurance situation from a general point of view in Alabama.—*Southern Medical Journal*, August, 1911.

Annuity Insurance for Professional Men.—The *British Medical Journal* states that government officials are, generally speaking, entitled to a pension on retirement, and most important business institutions have some scheme of superannuation for their staff, but, as a rule, a medical man has no retiring allowance to look forward to after a strenuous life unless he has had sufficient foresight to provide it out of his income. The average man who desires to set aside, say, $250 per annum to supplement his income on retirement and replace capital sunk in a practice requires the help of some system, or there is very apt to come a time when he fails to carry out his intentions. There are two courses open to medical men who intend to save a part of their income. They can invest through the Stock Exchange, earn a remunerative rate of interest, and take their chance of appreciation or depreciation in the amount they save. To follow this plan with any degree of success it is almost essential to have some special training in finance, and a great deal of time must be spent in selecting and watching the investments made. It would, of course, be necessary to reinvest the dividends as soon as received if compound interest is to be secured. After allowing for tax, brokerage, etc., it would be hard to realize more than 3½ per cent. as a net yield in this way. Let us suppose that, after allowing for income tax and brokerage, $250 per annum is successfully accumulated at the net rate of 3½ per cent. compound interest for twenty years, then the amount invested at the end of that period would be $7,315. In the event of death before completion of the twenty years only the savings to date with the interest thereon would be receivable. Under the alternative plan of effecting an annuity policy with a life insurance company the result from an investment point of view is much the same, but the responsibility and work are thrown upon the company. An annuity policy, however, presents two aspects—saving and protection. That is to say, a part of every premium paid is being saved for the assured, as in a savings bank, to be returned to him at a later date with compound interest, and the other part secures protection until the annuity age is reached, so that in the event of premature death the capital amount is payable in full. The benefits thus secured under an annuity policy in the event of death before maturity outweigh those obtainable by ordinary investment apart from the question of security. It would be necessary to spend more on the annuity policy to produce the same result, because in the event of premature death the full sum assured with bonuses to date would become payable. To provide $7,315, or an annuity of $640 (nearly $12.50 a week) at the age of sixty in the case of a healthy person aged forty next birthday, an annuity policy for $5,300 could be effected in a good office with bonuses at an assumed rate of about 38 per cent. per annum, namely, $2,015. The annual premium would be about $282.50. Comparing this with the annual saving of $250 the cost of the cover is only about $32.50. An annuity policy may fitly be described as a scientific form of saving. No trouble is involved, and there are no incidental expenses, the one important factor being the prudent selection of an office. The protection afforded during the period of saving should appeal specially to medical men. Another point not to be lost sight of is that the contract is elastic—the amount saved can be realized in a lump sum, or as a guaranteed annuity, as circumstances demand. If it be desired or necessary to discontinue the annual payments, a paid-up insurance can be secured proportionate to the number of annual payments already made. Thus five payments made out of twenty secure five-twentieths of the original sum contracted for.

Statistics of Suicide in the Registration Area.—H. A. Brown states that suicide as a cause of death is comparatively insignificant, the total number of reported suicides in 1909 amounting to only 8,402, or but 1.2 per cent. of the total number of deaths at all ages from all known causes (731,225) in the registration area. Of the total number of deaths from all known causes in this area, however, between the ages of twenty and twenty-nine years (56,979), 1,630, or 2.9 per cent., were due to suicide, as were 1,721, or 2.7 per cent., of those between the ages of thirty and thirty-nine years (numbering 62,803); 1,790, or 2.7 per cent., of those between the ages of forty and forty-nine years (66,674); and 1,480, or 2.0 per cent., of those between the ages of fifty and fifty-nine years (73,384). The percentages of suicides relative to the entire number show a steady increase from 19.5 per cent. during the period twenty to twenty-nine years to a maximum of 21.4 per cent. during the period forty to forty-nine years, and drop slightly to 17.7 per cent. during the period fifty to fifty-nine years. The decreases are then much more rapid, only one-tenth of 1 per cent. of the suicides occurring during the period from ninety to ninety-nine years, when five deaths from this cause were reported. As regards the methods of suicide it is noted that poison and firearms hold the chief place, these two accounting for nearly 58 per cent. of the suicides; about 26 per cent. are due to hanging and asphyxia (chiefly by illuminating gas); about 12 per cent. to drowning and cutting instruments, and the remainder to jumping from high places, crushing, and other or unspecified methods. Among males about one out of every twenty-eight persons between the ages of twenty-five and sixty-four years reported as engaged in agricultural pursuits, who died in 1909 in the registration area, committed suicide; about the same proportion occurred among those engaged in professional service; one to thirty-five in domestic and personal service; one to thirty-one in trade and transportation; and one to twenty-nine in manufacturing and mercantile pursuits.—*New York Medical Journal,* September 2, 1911.

Functional Tests of Cardiac Efficiency.—A. D. Hirschfelder states that the most popular of these is Gräupner's exercise test, in which it is found that the blood-pressure of strong hearts rises during exercise, while the blood-pressure of weak hearts falls. But recent studies have shown that when strain is placed upon the heart—the strong heart as well as the weak heart—there is a rise of blood-pressure which lasts for a while in both, in spite of the fact that the hearts are dilating. In many cases, however, the period during which the blood-pressure remains high in spite of dilatation is much more prolonged, so that from changes in blood-pressure alone one could not distinguish between the stronger and the weaker heart. The patient with a moderately weak but not absolutely failing heart usually responds with a much greater rise of blood-pressure than does the normal individual. On the other hand, the athlete responds to mild exercise with a fall of pressure. The change of blood-pressure, therefore, gives no true index of the dilatation of the heart, nor of the degree of cardiac tonicity, and, therefore, the mere blood-pressure and pulse-rate changes furnish evidence which is insufficient for the estimation of cardiac efficiency. The symptoms and sensations of the patient, his manner of breathing, his change of color, his general appearance, the degree of fatigue, and many other signs furnish a much more delicate test than the numerical changes in pulse rate or blood-pressure.—*Interstate Medical Journal,* June, 1911.

Medical Inspection of Delinquent Children.—S. Block discusses the importance of careful medical examination of children who are brought to court for various violations of the law. These children, if under sixteen years of age, are not looked upon as criminals, but are legally known as delinquents, and are sent to reformatories. At present neither New York State nor New York City officially recognizes a medical examiner for these cases. Various private organizations supply this want temporarily. In Brooklyn a special committee has considered this subject and has made the following recommendations: All children remanded from the Juvenile Court should be subjected to a medical examination. Voluntary examinations are undesirable; medical examiners should be paid for their work. There should be a scientific advisory council to the Juvenile Court of at least five members, at least three of whom should be medical men. This council should be appointed by the judges of the Juvenile Court. The duty of the members of the council should be to recommend examiners and interpret findings of the examiners, and act in an advisory capacity to the court. The simplest form of examination blank is preferred. The result of the examination should be handed to the judge of the Children's Court who has the case in consideration for final disposition. The committee is not prepared to answer the general question as to the relation between physical defects and juvenile crime, but if these examinations are systematically carried on they will answer that question in time. The relation between mental defects and juvenile crime is a fact. Medical examinations must sooner or later be resorted to in every Juvenile Court and it is time to recognize them as part of the machinery of justice. Not all cases that come to the courts are abnormal. Many of the cases are brought to the court for petty offences such as snowballing, etc. Only one-fifth of the cases are medical. These may be divided into two groups: 1, those physically abnormal; and, 2, those functionally, physiologically, or psychologically abnormal. The author presents illustrative types of the latter group. The service of the physician in this class of cases is summed up as follows: He should explain the results of the deficiency to parents, prevent injudicious marriages when possible, educate the public to discuss, at least, the matter of castration of degenerates, thus minimizing the danger of an unhealthy burden on the community. Most authorities agree on the last point, but not all. The physician should delve more deeply than heretofore into family histories, which often alone determine the diagnosis. He should recognize the fact that many traits of character are hereditary and that these are modified by individual environment. There are many criminal, drunkard, epileptic, or insane family trees. He should also be instrumental in correcting physical defects, removing enlarged tonsils, adenoids, and nasal spurs, putting glasses on weak eyes, syringing waxy ears, giving iron, arsenic, bromides, and thyroid in the thousands of cases now craving them. Then one in three hundred will not be mentally deficient. The physician should join the "big brother" movement and thus make a practical effort in a single case.—*American Journal of Obstetrics and Diseases of Women and Children,* May, 1911.

Statistics of Coal-Mining Accidents.—The figures collected by the United States Geological Survey show that in 1907 in 22 States that produce 98 per cent. of American coal there were 3125 men killed and 5316 injured; in 1908, 2450 were killed and 6772 injured. In 1907 one man was killed for each 206 employed; in 1908, one for each 278 employed. In 1907 one man was killed for each 145,471 tons of coal mined; in 1908, one man was killed for each 167,545 tons mined. During the decade ending with 1908, 19,469 men were killed in the coal mines. According to figures compiled from the mining reports of Pennsylvania and Illinois for the decade ending with 1908, the average mine employee of these States has one chance in 324 of death from his year's work, and one chance in 138 of injury. If he looks forward to ten years' employment in the mines, he has one chance in 32 of fatal injury, and one chance in 14 that a non-fatal accident will befall him. Over thirty per cent. of coal-mine casualties are fatal.

Book Reviews.

Allgemeine und spezielle Pathologie des Zwerchfells. Supplemente zu H. Nothnagel, Spezielle Pathologie und Therapie. Von Privatdozent Dr. Hans Eppinger in Wien. Mit 31 Abbildungen im Text. Price, 6.50 marks. Wien und Leipzig, Alfred Holder. 1911.

Supplementary parts are now being issued to the invaluable Nothnagel System of Medicine which bring together certain phases of disease or certain regions which were not exhaustively handled in the original sections. Eppinger has prepared an excellent supplementary monograph on the development and physiology of the diaphragm, its general pathology, and the special lesions of this muscular organ, which forms an extremely useful and up-to-date summary. The bibliography is very full. An index of course has been omitted.

A Treatise on Diagnostic Methods of Examination. By Professor Dr. Hermann Sahli, Director of the Medical Clinic, University of Bern. Edited, with additions by Nathaniel Bowditch Potter, M.D., Assistant Professor of Clinical Medicine at Columbia University (College of Physicians & Surgeons), New York; Visiting Physician to the New York City Hospital, to the French Hospital, and to the Hospital for Ruptured and Crippled. Second Edition, Revised. Authorized Translation from the Fifth Revised and Enlarged German Edition. Price $6.50. Philadelphia and London: W. B. Saunders Company, 1911.

This volume is a veritable mine of information on the subject of diagnostic methods. The rapidity with which these have grown within recent years and the complexity which they have attained are a source of bewilderment to the practitioner who would fain appropriate at least a small portion of the vast estate. The growth of this subject is partly shown in the fact that the present edition contains 220 pages in excess of the former, or a total of 1229 pages. The extensive alterations and complete revisions that characterize the fifth or latest edition of the German work compelled the editor of the English edition to adhere strictly to the German text, without adding comment of his own. The use of a thinner paper and of finer type in certain places has enabled the publishers to accommodate the larger material in a volume that is no thicker than the first edition. Among the new subjects and changes that have been introduced in this edition may be noted the following: Géraudel's investigations on icterus; edema considered in the light of studies by Metzer and Starling; the determination of cutaneous electric resistance; a new theory on the nature of fever; the teleology of dyspnea; and the graphic record of types of respiration. In the chapters on hemodynamics are noted sections on pseudotachycardia and pseudobradycardia; on dynamic palpation; on sphygmobolometry; on the method of taking simultaneous records; on various new instruments such as Mackenzie's polygraph; a chapter on simultaneous records of pulses of different arteries in the diagnosis of aortic aneurysms; new sections on arterial maximum pressure, the absolute sphygmogram, the ventricular nervous pulse and other refinements in hemodynamics. In the chapter on precussion a special section is devoted to recent investigations on the theory of the percussion notes; and in the chapter on auscultation there is described a graphic method of recording the cardiac sounds and a method of chronoscopic determination of the length of the systole. With the chronoscale devised by Sahli; hundredths of a second may be directly read. In palpation the importance of the Siendelenberg position is emphasized. There are described a host of new methods in the examination of the stomach and intestines. Modern rectoscopy is discussed at length. The section on urine examination contains many additions, of which may be mentioned the methods for the differentiation of various forms of albuminous substances and new methods of quantitative determination of sugar. Among the new topics discussed in the chapter on the sputum may be mentioned the nonacid fast form of tubercle bacillus, and Bordet's whooping cough bacillus. There are numerous changes and additions in the chapter on the blood, including recent observations in the blood in Banti's disease, multiple myeloma, purpura, scorbutus, and many other conditions. Among the additions in the section on the nervous system are the testing of the sensory effect of faradic vibrations and of muscle contraction, alternating contractility of muscles under electric stimulation, and psychogalvanic reflex phenomena. Among the descriptions of the reflexes one notes the absence of any reference to Brudzinski's reflex (signe de la nuque) or of the contralateral reflex, both of which are valuable in the diagnosis of meningitis. This partial summary of some of the newer methods of diagnosis that have been added to Sahli's work shows that one can ill afford to omit this book from one's reference library.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; assisted by Leighton F. Appleman, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. June 1, 1911. Price $6.00 per annum. Philadelphia and New York: Lea & Febiger.

The current number contains Coley's contribution on Hernia; Gerster's on Surgery of the Abdomen, exclusive of Hernia; J. G. Clark's on Gynecology; Stengel's on Diseases of the Blood, etc.; and Jackson's on Ophthalmology. The style and the value of this publication are too well known to need more than the mention of the new number. As is usual in the June number, Dr. Clark gives a most useful summary on Cancer. It will be noted that Dr. Gerster supplied the article so long furnished by Dr. Foote.

Radiométrie Fluoroscopique. Par le Docteur H. Guilleminot, Attaché au Laboratorie des Travaux Pratiques de Physique Biologique de la Faculté de Médecine de Paris. Avec 12 figures dans le texte. Prix 2 fr. 50. Paris: G. Steinheil, 1911.

The determination of the dosage of *x*-rays is a subject that is still in its infancy. Nevertheless important progress is being made. The property which the *x*-rays possess in common with light waves of short wave-length, with ultraviolet rays, and with radium emanations, of rendering phosphorescent crystals of platinocyanide of barium, has been utilized as a means of actually measuring the intensity of the *x*-rays. The author describes in this volume his method of measuring the *x*-rays by their fluoroscopic power. He also describes the applications of this method in radiography, in radiotherapy, in the analysis of the *x*-rays, in the determination of the efficacy of *x*-ray filters, and in the determination of the dosage of radium emanations.

Die Immunitätswissenschaft. Eine kurz gefasste Uebersicht über die Immunotherapie und Diagnostik für praktische Aerzte und Studierende. Von Dr. Hans Much, Oberarzt am Eppendorfer Krankenhause. Mit 5 Tafeln und 6 Abbildungen im Text. Price $2. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1911.

Comparatively early in the history of the development of serology Much published an excellent treatise for nonspecialists on what was then known concerning the subject. Since that time a considerable number of similar books have been written, and widely read, so that at present the practical aspects of this field of investigation are fairly well known. None the less the appearance of the author's present and much larger volume must be greeted with a great deal of satisfaction. This is the case not alone owing to his reputation as an investigator who has made many valuable contributions to the theory of immunology and serotherapy, but chiefly, perhaps, on account of his experience as a clinician in applying the results of his own work and that of others in actual practice, and because of his unprejudiced judgment of the effectiveness of these procedures. The book is therefore one that is most likely to appeal to practitioners, for whom indeed it evidently was written, for the therapeutic side has been greatly emphasized, and less space devoted to technical methods. For the general medical reader the book is a model and it appears to the reviewer that the difficulties of providing satisfactory explanations of the complicated phenomena involved without undue excursions into the realms of theory have been most happily overcome. The principles underlying our conceptions of anaphylaxis, the action of opsonins and aggressins, the meiostagmin and Wassermann reactions, etc., are very clearly discussed and the technique of making sera and vaccines and of carrying out specific agglutination and precipitation tests is described with sufficient detail to make the method easy of comprehension. Added to the excellence of the material is the author's very agreeable and simple style, which should render the book easy to read even for those not very well versed in the German language. It must be considered as one of the most useful contributions to the literature of the subject that has yet appeared and deserves the attention of every one at all interested in the progress of immunotherapy.

Golden Rules of Pediatrics. Aphorisms, observations, and precepts on the science and art of pediatrics; giving practical rules for diagnosis and prognosis, the essentials of infant feeding, and the principles of scientific treatment. By John Zuhorsky, A.B., M.D., Clinical Professor of Pediatrics, Medical Department, Washington University, St. Louis; ex-President of the St. Louis Pediatric Society; Attending Physician to the Bethesda Foundlings' Home and the St. Louis Children's Hospital; Member of the American Medical Association and St. Louis Academy of Science; Author of "Baby Incubators," etc. With an Introduction by E. W. Saunders, M.D., Emeritus Professor of Diseases of Children and Clinical Midwifery, Medical Department, Washington University, St. Louis, etc. Price $2.50. St. Louis: C. V. Mosley Company, 1911.

The title page indicates the scope of this book, the first edition of which has apparently enjoyed a wide popularity. The mature experience of the author enables him to speak with authority, and those who specialize in diseases of children will find that the rules laid down in this book are fully in accord with their own experience, while the general practitioner will find it a most entertaining review of his own scattered knowledge of the subject. The book deserves wide circulation.

Disease in Bone and Its Detection by the X-Rays. By Edward W. N. Shenton, M.R.C.S. (Eng.), L.R.C.P. (Lond.), Sen. Surg. Radiographer, Guy's Hospital. With illustrations. Price $1.60. New York: The Macmillan Co., 1911.

This is a small book of 72 pages, nevertheless the importance of its subject matter is out of all proportion to its size. An experience extending over a period of fourteen years has enabled the author to reach the conclusion that the *x*-rays should not be relegated to the detection of coarse and obvious lesions, but should be employed in the detection of early lesions. It is pointed out that many diseases are clinically alike, but are radiographically different, *e.g.* tubercle and osteoarthritis, malignant disease, and chronic inflammatory trouble in the shafts of long bones. It is predicted that the examination for varying densities in bone will become a routine practice in surgical, if not in medical, practice. There are various forms of thinning of bone that occur in many chronic diseases, including alcoholism. An increased transparency of bone is observed in cases of malnutrition and in anemia, and as the result of keeping a bone at rest. The main part of the book is devoted to a discussion of the radiographic appearances accompanying inflammation in bone, tuberculous disease, osteoarthritis, growth in bone, and osteomalacia. The series of 46 photographic illustrations accompanying the text are remarkable for their clearness.

Clinical Symptomatology. With Special Reference to Life-Threatening Symptoms and their Treatment. By Alois Pick, Professor of Medicine, University of Vienna, and Adolph Hecht, Pediatrician, St. Anne's Hospital, Vienna. An authorized translation under the editorial supervision of Karl Konrad Koessler, M.D. (University of Vienna), Instructor of Clinical Medicine Rush Medical College, in Affiliation with the University of Chicago. New York and London: D. Appleton & Company, 1911.

The title of this volume clearly indicates its purpose and scope. The authors state in the preface that the number of morbid processes in which there exists a specific therapy is very small and that the physician is obliged to select those symptoms from the total picture, which, if successfully combated, will render the greatest benefit to the patient. The life-threatening symptoms that sometimes develop insidiously test the resourcefulness of the physician. Dangerous symptoms are frequently latent, not suspected by the patient, and overlooked or unrecognized by the physician until too late. The present volume is a systematic discussion of these symptoms, their significance and treatment. It is difficult to classify this book, combining as it does the features of a textbook in diagnosis with those of a manual on treatment. An idea of the scope of the subject matter may be conveyed by the titles of some of the chapters, as follows: General symptoms, disturbances of respiration, dyspnea, and asphyxia, pain in the chest, cough, vomiting, diseases of the intestines, examination of the abdomen, hemorrhage, severe general infections, sleeplessness, etc. The eminence of the authors as clinicians and teachers is stamped on every page, in the careful presentation of the various topics, and the inclusion of the latest contributions to the arts of diagnosis and treatment. The volume is a veritable mine of information on these subjects. To the skill of the translator must be accorded the credit for the excellent literary style with which the text is garbed. The volume represents one of the most valuable contributions made within recent years to medical literature.

Funktionelle Diagnostik und Therapie der Erkrankungen des Herzens und der Gefässe. Von Professor Dr. Aug. Hoffman, o. Mitglied der Akademie für prakt. Medizin und Direktor der medizinischen Klinik in Düsseldorf. Mit 109 Abbildungen und einer farbigen Tafel. Wiesbaden: Verlag von J. F. Bergmann; New York: G. E. Stechert & Co., 1911.

In this volume of 483 pages the author presents in extended form the content of his lectures on diseases of the circulatory organs, as delivered at the Academy for Practical Medicine, at Düsseldorf. Keeping in mind the practical needs of the physician, he makes the subjects of diagnosis and therapy of cardiac insufficiency the starting point of a complete exposition of circulatory disturbances. This subject is presented with characteristic German thoroughness, with full appreciation of the extensive developments of the past ten years in the physics and mechanics of cardiac pathology. As examples may be mentioned the excellent description of *x*-ray diagnosis of cardiac disease, electrocardiography, the other numerous methods of graphically recording the events in the cardiac cycle and the variations in blood pressure, all of which are profusely illustrated. The volume is divided into three parts. The first deals with the subject of general diagnosis. The second deals with the subject of special diagnosis. The third part takes up the subject of the functional therapy of diseases of the heart and blood vessels. It is difficult to single out any one portion of the work for special commendation. The section on therapeutics is particularly complete, discussing in detail the various physical, hydrotherapeutic and medicinal measures. Appended to each chapter is a comprehensive bibliography. The volume is handsomely printed on good paper.

Materia Medica Step by Step. By Arthur W. Nunn, F.C.S., Pharmaceutical Chemist, Materia Medica Medallist. Price $1.40. Philadelphia: P. Blakiston's Son & Co., 1911.

This little work is really an introduction to pharmacology, and does not treat of Materia Medica as it is generally understood. The plan of the book is based on the arrangement of the British Pharmacopeia, and the volume is evidently intended as an introduction to that work. The author has been unusually successful in making clear and simple what beginners generally find uninteresting and irksome.

Handbuch der speziellen Chirurgie des Ohres und der oberen Luftwege. Herausgegeben von Dr. L. Katz, Spezialarz für Ohren, Nasen, und Halskrankheiten in Kaiserslautern; Dr. H. Preysing, Professor der Ohrenheilkunde, ord. Mitglied der Akad. für prakt. Medizin zu Cöln a Rh.; und Dr. F. Blumenfeld, Spezialarzt für Nasen, Hals, und Lungenkrankheiten in Wiesbaden. 1 Bd., Lieferung 4-5. Price 9 Marks. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1911.

The scope of this work has already been alluded to in former reviews in the Medical Record. The present number represents the third instalment of the first volume, and continues the subject of the topographical anatomy of the nose and of its accessory cavities, and begins the description of the topographical anatomy of the ear. There are in this number seventy-two full-page plates which represent the very optimum in artistic illustration.

Hautkrankheiten sexuellen Ursprungs bei Frauen. Von Dr. Oskar Scheuer, Facharzt für Haut-und Geschlechtskrankheiten in Wien. Price, 9.50 marks. Berlin and Vienna: Urban & Schwarzenberg; New York: Rebman Company, 1911.

Of considerable interest not only to dermatologists, but also to obstetricians and gynecologists, is the subject of the cutaneous affections associated with changes in the sexual apparatus in women. This is a topic which has interested physicians from time immemorial. In a monograph of 204 pages the author covers the entire field of the relation between the skin and the physiology and pathology of the female sexual organs. The cutaneous manifestations occurring at puberty, during menstruation, in chlorosis, during pregnancy, parturition, the puerperium, at the climactric and as the result of castration and of various diseases of the sexual organs are all fully described. The author, in addition to his own extensive experience, presents the results of a comprehensive survey of the literature and appends a complete bibliography.

Vicious Circles in Disease. By Jamieson B. Hurry, M.A., M.D. (Cantab.), ex-President Reading Pathological Society. With Illustrations. Price $2. Philadelphia: P. Blakiston's Son & Co., 1911.

The term which forms the title of this book is one with which the medical student becomes acquainted early in his career, and which he uses frequently ever after. Few persons, however, have thought enough about the matter to realize how extremely common the establishment of such a relation between cause and effect is in conditions of the most varied sorts. The author has set himself the task of collecting such instances and elucidating each by a paragraph or two of terse discussion. The first nine chapters are devoted to the circles associated with the nervous system, the cardiovascular system, etc., and in the final three the genesis of the circle and the manner in which it may be broken by natural means or by treatment are discussed. Appropriate diagrams illustrate the sequence of events and emphasize the points made in the text.

Tratado de Ginecologia. Por el Dr. Miguel V. Fargas, Catedrático de Obstetricia y Ginecologia de la Facultad de Medicina de Barcelona; Miembro de la Real Academia de Medicina y Cirugia; ex-Presidente de la Academia y Laboratorio de Ciencias Médicas de Cataluña; Miembro del Instituto Rubio de Terapéutica operatoria de Madrid; Miembro honorario de la Sociedad de Obstetricia y Ginecologia de la Universidad Imperial de Moscou, etc. Segunda Edición, revisada. Tomo Primero: I. Generalidades; II. Enfermedades de la Vulva y Vagina. Tomo Segundo: III. Enfermedades del Utero; IV. Enfermedades de los Anexos. Barcelona: Salvat y C. a S., en C., 1911.

The first edition of this work appeared eight years ago, when it was accorded a warm reception by the profession in the various Spanish-speaking countries. As Professor of Obstetrics and Gynecology in the University of Barcelona, and with an experience of twenty years in the practice of gynecology, an experience comprising 18,000 cases, the author has impressed upon this work the stamp of mature scholarship and practical knowledge. The subject of gynecology touches very closely every other branch of medicine, and he who would aspire to authority in this as in other specialties, must have a vision that is not restricted by the boundaries of his particular province. It is this breadth of view that distinguishes the present work. In its two volumes, and its total of 1,284 pages, it presents a comprehensive survey of the entire field of modern gynecology. The first volume consists of two parts. The first of these, which comprises the greater part of the volume, deals with the general aspects of gynecology—anatomy, physiology, methods of examination, medical and local treatment, and the principles of operative treatment. The author presents in minute detail a description of the gynecological armamentarium, from the arrangement of office fixtures and the laboratory equipment, to the selection of instruments. The description of the surgical technique specially applicable to gynecology is masterly. The second part of the first volume deals with the diseases of the vulva and vagina. The second volume discusses the diseases of the uterus and those of the adnexa. The various operative procedures are described in detail, and the successive steps in the operations are shown with the aid of many photographic and other illustrations. The author gives evidence of an attitude of conservatism and of a full appreciation of the medical and physical methods in the treatment of the numerous conditions that arise in the practice of the gynecologist as well as of the general practitioner.

Hospital Management. A Handbook for Hospital Trustees, Superintendents, Training School Principals, Physicians, and all who are actively engaged in promoting hospital work. By Charlotte A. Aikens, Author of "Hospital Training-School Methods and the Head Nurse"; "Primary Studies for Nurses"; "Clinical Studies for Nurses." 12mo, 488 pages. Illustrated. Cloth, $3.00 net. Philadelphia and London: W. B. Saunders Company, 1911.

There is no doubt that this book will fill a long-felt want among those who are connected with hospitals, both as officers and as trustees. To the former a practical classification of the various duties of employees is given, together with many valuable suggestions as to management; and to the latter class a fund of information all trustees should know—and few do. The book is a compilation of nineteen chapters, written by as many authors on the several subjects taken up.

Chapter I is on "The American Hospital Field," and on the whole is a most able paper. Dr. Emerson, in taking up that new and most necessary branch of hospital work, "social service," gives to us a clear, concise idea as to the value of a branch of hospital work which is now absorbing the attention of all institutions which are striving to get away from the old idea that their responsibility ceases when the patient leaves their doors. Dr. Emerson's observations on hospitals for special work may not meet with the approval of many medical men. In this age of specialism our general hospitals are not prepared to devote to special branches of surgery the attention that is given in institutions equipped solely for that purpose; but on the whole, what he says is true—at least it will be true when our hospitals have advanced to a higher state of perfection and that germ of sure destruction, jealousy, is eliminated. To one who is contemplating building a hospital this work will prove a veritable compendium. The wards, kitchens, halls, engine-room, offices, and all other departments are treated in turn.

The chapter on "Superintendent of Training Schools" is worthy of special mention. The author of this chapter, Miss Aikens, shows us that she is a woman of great experience on this subject. She has ably handled the question, and it should be read by every person occupying that position.

Perhaps, after all is said, this book will appeal especially to the man who is a member of the board of trustees of some hospital. It will tell him, in a concise form, exactly what a hospital should do, and how it should be run, from the scrubwoman up to its financing, and what is expected of the various officers connected with the institution. "Hospital Management" should prove a valuable addition to our literature on this subject.

Merck's Manual of the Materia Medica. A Ready-Reference Pocket Book for the Physician and Surgeon. Containing names of the chemicals and drugs used in modern medical practice, with their chief synonyms, physical form and appearance, solubilities, percentage strengths and physiological effects, therapeutic uses, modes of administration and application, regular and maximum dosage, incompatibles, antidotes, precautionary requirements, etc.; a table of therapeutic indications, with paragraphs on bedside diagnosis, and a comprehensive collection of prescription formulas, embracing also the newer remedies of established merit; a classification of medicaments; and miscellany, comprising poisoning and its treatment; a comprehensive dose table of chemicals, drugs, and galenicals; urinalysis and examination of urinary deposits; approximate metric equivalents and various useful tables, etc. Compiled from the most recent authoritative sources. Fourth Edition. St. Louis, New York, Rahway: Merck & Co., 1911.

It is sufficient to mention the appearance of a new edition of Merck's Manual; a perusal of the title page will show what it contains.

The Care of the Baby. A Manual for Mothers and Nurses. Containing Practical Directions for the Management of Infancy and Childhood in Health and Disease. By J. P. Crozer Griffith, M.D., Clinical Professor of Diseases of Children in the Hospital of the University of Pennsylvania; Physician to the Children's Hospital; Consulting Physician to St. Christopher's Hospital for Children; Member of the American Pediatric Society and of the Association of American Physicians; Corresponding Member of the Société de Pédiatrie of Paris. Fifth Edition, thoroughly revised. Price $1.50. Philadelphia and London: W. B. Saunders Company, 1911.

The book, the first edition of which was published in 1895, is so well known to the profession that comment upon it at this time would seem superfluous. It has been carefully revised and brought up-to-date, and maintains its former standard as a reliable book for the guidance of mothers and nurses in the management of infants and young children.

Nothelferbuch. Leitfaden für Erste Hilfe; bei plötzlichen Erkrankungen und Unglücksfällen. Herausgegeben von der Medizinalabteilung des Königlich Preussischen Ministeriums der geistlichen, Unterrichts und Medizinal-Angelegenheiten. Mit zahlreichen Abbildungen im Text. Berlin: Verlag von August Hirschwald, 1911.

First aid to the victim of an accident or to one who has been taken suddenly ill, is presented briefly and at the same time thoroughly in this excellent manual of 159 pages. It is intended as a textbook for the use of classes taking a short course of instruction in first aid. The first chapter gives an outline of such a course for the use of the teacher, a course that may be completed within the limits of twelve to fifteen lessons. The text which is admirably supplemented with a large number of illustrations contains all the well-known features of the first-aid manual, together with many useful hints on the subject of nursing and disinfection, and a description of the German statutes relative to quarantine, notification, and compulsory insurance.

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Annual Meeting Held in Philadelphia, Pa., May 29, 30 and 31, 1911.

Monday, May 29—First Day.

Regional Anatomy of the Upper Air Tract.—Dr. George McClellan of Philadelphia directed particular attention to the deviations in the course of the esophagus and to the folds of mucous membrane usually encountered at such points. He also laid stress upon the innervation of the air passages, particularly with reference to the parts supplied by the recurrent laryngeal nerve, voicing the opinion that the accessory fibers from the spinal accessory nerve as it emerges from the skull combine with the vagus nerve and ultimately help to form the recurrent laryngeal nerve.

Vasomotor Rhinitis (Apart from Hay Fever).—Dr. E. Fletcher Ingals of Chicago considered this a nasal condition differing from the ordinary forms of hyperesthetic rhinitis, hay fever, rose colds, etc., being characterized by excessive intumescence of the turbinal bodies, which are very pale, excess of thin, watery secretion, intense tingling in nose, exceeding chronicity. The attack was brought on by exposure to heat or cold, various irritants, and other unknown causes. The disease had been prevalent around Chicago the past winter; the general health at first was not affected. The treatment was very unsatisfactory, as the nose was intolerant of applications, and no remedy was found that afforded more than slight temporary relief, and that only at times.

Vasomotor Disturbances of the Upper Air Tract.—Dr. Charles W. Richardson of Washington, D. C., called particular attention to the difference between the perennial and paroxysmal vasomotor catarrh, and discussed only the perennial type. He referred to the investigations of Bidder and Volkmann, as well as Buch's experiments on the sympathetic, and to the fact brought out by these investigators that the sympathetic nerve was non-sensitive only in a healthy condition. When the nerve became hyperemic it was extremely sensitive to pain. Through this hyperemic nerve various reflexes of a sensory, motor, or vasomotor catarrh could be produced. The speaker divided the perennial type of vasomotor catarrh into four different classifications, treated largely of the constitutional character of these disturbances, and considered that they were more of a general type than due to local inflammatory changes within the passages, the toxin or irritant being produced through changes in the fluids and tissues of the body.

Dr. Delavan of New York, in referring to a case cited by Dr. Ingals, considered one of the most interesting features to be the fact that after the use of the serum treatment the patient, although exposed to quite as inclement weather as formerly, had not nearly so severe symptoms as previous to its use.

Dr. Coakley of New York said that he had seen many of these cases and believed local treatment to be of little or no avail. He considered these conditions to be dependent on some derangement of the internal secretions, attended by a peculiarly irritable condition of the nasal mucous membrane.

Dr. Coffin of New York agreed with the former's remarks, and gave briefly the report of one of his own patients, in whom the condition was shown to be due to some autointoxication.

Dr. B. R. Shurly of Detroit stated that these conditions were almost exclusively associated with people of high tension and peculiar nervous temperament, nearly all patients being among the intellectual classes. He considered local treatment inadequate, and suggested that this condition in the nose was usually associated with a vasomotor disturbance in some other possibly remote part of the body. He believed that the internal secretions played a very important part. In the line of therapy his best results had been obtained through the use of valerian and other general sedatives, and by the hypodermic use of citrate of iron, which had a very quick and sharp effect on the general nervous system and blood stream, adding tone to the entire vasomotor system.

Dr. Thrasher of Cincinnati mentioned two expedients for the relief of the most troublesome symptoms; one was the free incision of the turbinal bodies, giving free exit for the accumulated fluid; the other, the hypodermic use of adrenalin in doses of from 5 to 10 minims (1-1000) once or twice a day.

Dr. Logan of Kansas City called attention to the cauterization of the highest part of the triangular cartilage, which he had found of more value in relieving the turgescence than any other local application to the turbinal body. He also mentioned good results from the use of bromides, and the application of the galvanocautery to the anterior tip of the turbinate and local area of the triangular cartilage.

Dr. Norval H. Pierce of Chicago agreed with regard to the beneficial results obtained from following Professor Killian's methods. He cited an interesting case of vasomotor disturbance due to the eating of raspberry pie, to which the patient was extremely susceptible.

Dr. Coolidge of Boston considered the question from the standpoint of lack of immunity in the body fluids, this making some susceptible and others not. He laid stress upon the similarity existing between vasomotor rhinitis and the various infectious fevers, such as measles, scarlet fever, etc., in their manner of onset, and also regarding immunity.

Dr. Myles of New York advocated the cutting out of a section of the tubercle of the septum, making a complete section down to the junction of the perpendicular plate of the ethmoid where the triangular cartilage meets it. This was done either under cocaine or adrenalin. His theory was that by this procedure the transmitter of the irritation either to Meckel's ganglion or to the brain center was cut.

Review of Eighty-one Cases of Inflammation of the Frontal Sinus.—Dr. George L. Richards of Fall River presented this comparative study. Both sinuses were involved in 23.5 per cent., the left alone in 32 per cent., the right alone in 44.5 per cent. The question as to which sinus was involved depended upon the anatomical conformation of the nose and the relation of the frontonasal outlet to the septum and to the turbinate. Sixty per cent. of the cases were acute, 7 per cent. subacute, and 33 per cent. chronic. Pus was found in 92 per cent., and five cases, or 8 per cent., were designated as gas cases; that is, the symptoms were apparently due to the closure of the outlet of the frontonasal canal, with consequent sense of pressure, due to the expansion of the air or gas within the sinus. In 14 cases the antrum also was involved. As to treatment, 65 cases were treated intranasally, and in 16 radical operations were done. That is, 81 per cent. were found to be curable intranasally, 20 per cent. required some type of external operation. Sixty-six cases were considered as cured. The others still had an occasional recurrence of acute attack, or small amount of pus discharge still remained. For the permanent comfort of patients with frontal sinus trouble it was essential that the frontonasal duct remained open, unless the sinus were entirely obliterated. As to the general method of treatment, intranasal methods should be tried for a long time, and would usually result either in a cure or in so great amelioration of symptoms that the patient would not submit to any more radical operation. There were other cases of extensive involvement of the ethmoid cells which would require some type of external operation before final cure was accomplished.

Attenuated Types of Suppurative Sphenoiditis in Relation to So-called Postnasal Catarrh, to Headache with Mental Daze, and to Asthma.—Dr. W. E. Casselberry of Chicago read this paper, stating that the sphenoid sinus being out of sight was out of mind until adrenalin's vasoconstrictor effect availed to facilitate reaching it by operation, when the frequency of its infection as a primary source of postnasal discharge became evident. The secretions of the attenuated infections appeared, not as typical pus, but as variously modified purulоid products, most, though not all, of which might be grouped in two classes. First, those varying from pus to mucopus, which did not form a varnish-like film nor induce atrophy, but tended rather toward edematous hyperplasia, an intensification of which, lacking previous emphasis, was a prolific polypoid exudate, forming layer upon layer at the site whence polyps had been removed, as if a fresh growth of polyps had sprung up over night. The second class included the viscid mucilaginous, sometimes fetid, secretions, which when copious formed into long ropey strings, defying ordinary means of expulsion. When rather scanty they varnished the pharyngeal wall, inducing atrophic or dry pharyngitis, and accumulated in the nasopharynx in brownish splotches, comparable only to liquid glue, which when "set" formed adamantine-like crusts, liable to require the leverage of a probe to pry them loose. The osteum sphenoidale itself was located out of sight, nor was it visible by reflection from the rear unless marked by a bead of pus, a protruding polypus, or a probe. However, in the rhinoscopic image, just outside the osteum, could be seen a portion, 1 cm. in length, of a probe which had been properly inserted in the sphenoid sinus. As this means of verification gave the most satisfactory assurance of precision to the diagnostic tests which followed it, the author had sought by perfecting the technique of the rhinoscopic examination with the cannular probe in position to render it generally available. Thus, to prevent the cannular probe from slipping out it was anchored to the dorsum of the nose by a flexible wire and a piece of rubber plaster. To facilitate the anchoring and to avoid the annoyance of having to withdraw the probe to reintroduce a cannula for the irrigation and aspiration tests, a combination cannula and probe of original design was used. Tapping the inner wall of the sinus served to elicit another characteristic sign, which was termed the sphenoid click, as if the bone were almost but not quite bare, accompanied by a leaden metallic click, a combination peculiar to the healthy sphenoid and not due to dead bone. In diagnosis the irrigation test was of first importance. From fifty to sixty private cases had been recorded under the diagnosis in part of suppurative sphenoiditis, although in less than one-eighth of the number was the infection limited absolutely to the sphenoid without involving the postethmoid cells or other sinuses. With respect to postnasal catarrhal conditions, including atrophic or dry pharyngitis, the conclusion was reached that, after the exclusion of antrum disease, adenoid growth, or clefts, Thornwald's bursa, and pronounced posterior turbinated hypertrophies, practically all other chronic postnasal purulоid discharges were due to suppurative sphenoiditis, either alone or with implication of other sinuses. With reference to headache: The best description was by a university professor, who said "it was a boring pain toward the middle of the head far back between the eyes." More often it was located in the back of the head, but connected also with pain far back in the eyes, and next the top of the head or the side near the top, or radiating from the ear and mastoid to the top of the head; one-third of the sphenoid cases suffered from occipital or parietal headache; in one when the probe penetrated the sphenoid sinus it liberated an orange-yellow discharge, with cessation of the pain. Another was conscious of a dazed mental state, on whom a double Hajek operation resulted in free drainage of the sphenoids and cessation of symptoms. Commonly when, with a probe or sphenoethmoid cutter, one touched the postethmoid and adjoining face of the sphenoid, the patient exclaimed at suddenly feeling a sharp pain at one or more of these five points—the back of the head, the top of the head, the eyes, the ear, and upper jaw. Merely touching with a cotton applicator the site of the spenopalatine ganglion had caused patients to remark that it was the right spot, as it excited the same kind of pain or suggestion of neuralgia as that for which they sought relief. The ganglion bordered the floor of the postethmoid cells and the sphenoid wall, and connected with the nerves distributed to the five painful parts, which indicated that sphenoethmoid disease was capable of exciting the ganglion, and so of causing headache of the type described. Nevertheless mere distension of the sinus by fluid or gases could cause headache of the deep-seated boring description. With reference to asthma: About one-third of the series were asthmatic subjects; in several the sphenoid region was a dominating feature, and in a few it was the only site of attachment of polyps. A recurrence of asthma was observed in conjunction with an acute exacerbation of chronic sphenoiditis, also with a severe initial attack of sphenoiditis. Believing the benefit of removal of the nasal exudative features of asthma to be proportionate to the thoroughness of the operation, the author had of late years supplemented earlier treatments by removing any residual polypi found in the sphenoethmoid sulcus, with the effect of gaining a distinct reduction in the patient's residual asthmatic tendency. Twenty-four intranasal operations were performed on seventeen private patients. Usually only local anesthesia is employed. Resection of the middle turbinal was necessarily the first step, and the bulla, with other anterior ethmoid cells, if found diseased, were also eliminated on the way to the posterior group which then came in view. This the author called the back-bulla, as keeping this resemblance in mind aided in distinguishing it in the foreshortened perspective. The postethmoid group was dealt with as one structure, for one could not know, nor was it essential to know, how many individual cells it contained. The dominating principle of the treatment was free drainage or as nearly free as might be consistently possible. The palliative treatment was based on the principle that if the posterior nares and nasopharynx were kept clear of accumulated sphenoid discharge the catarrhal symptoms and irritation exterior to the sphenoid outlet would tend to subside and the sphenoid drainage be improved in so far as the exterior swelling had impeded it. The same principle must have pertained to the amelioration of the symptoms before the real condition was thought of. As the cleansing process must be regularly maintained, it was essential to instruct the patient in a simple but efficient method—requirements met by the postnasal type of douche with an alkaline solution weak enough to be devoid of irritating effect. With regard to the extent to which the sphenoid wall and postethmoid cells might regenerate it was believed additional portions might need to be excised but that eventually they remained open. With regard to a cure, to approximate ordinary conditions, a less rigid standard of cure than total suppression would suffice, few individuals being altogether free from disordered secretion. If then nine-tenths or more of the distress and disability incidental to the postnasal discharge were eliminated, material mitigation of the asthmatic feature afforded, and the headache with possible mental deterioration wholly remedied, it amounted to a practical cure. In this sense a large majority of sphenopostethmoid sinus infections of the attenuated types specified were curable by the methods described.

Foreign Bodies in the Antrum.—Dr. James E. Newcomb of New York reported the case of a middle-aged man referred to him with postnasal discharge. Examina-

tion revealed in addition the existence of pulmonary tuberculosis. At the time of his first visit the patient was not transilluminated and the source of the discharge was not definitely made out. Under cleansing he remained without definite benefit and was seen again some months later. At this visit he was transilluminated and an empyema of the left antrum was definitely discovered. His general condition seemed to forbid anything more radical than perforation through a vacant tooth socket and insertion of a Myles' rubber antral tube. With this the drainage afforded was perfect and the patient was much relieved. He was very nervous and constantly working with his tongue at the tube, which was closed with a wooden obturator. On one occasion, while in the doctor's office, both tube and obturator were thrust into the antrum. It was supposed at first that they had fallen on the floor and search was made for them but they were not found. It was then surmised that they were in the antrum. A skiagram made by a competent operator failed to reveal them. The patient was instructed to keep the cavity clean and to return after he came back from the mountains, whither he desired to go for the summer. While there (patient's statement) he fell into the hands of a dental student who succeeded in removing first the tube and then the obturator and with the same delicate forceps with which Dr. Newcomb had failed. The patient's condition at the time of the accident was not good and he stood manipulation very badly at his office visits. After his return the pulmonary lesion steadily progressed and he died from it, with laryngeal involvement. Dr. Newcomb has succeeded in finding 50 cases of a similar accident recorded in the last 20 years, and gave a list of references, alluding to some of the more interesting ones. The proper treatment of such cases was to open the antrum through the canine fossa provided search through a natural or artificial opening through a tooth socket did not reveal the foreign body. A small electric light should be used to examine the cavity and the latter should receive at the same time the treatment its condition seemed to indicate.

Dr. Makuen of Philadelphia mentioned a case of foreign body in the antrum consisting of the retention of a portion of gauze packing, in the removal of which he was compelled to curette the whole cavity over again.

Dr. Casselberry of Chicago considered that in the majority of cases where tubes were worn the patients became addicted to the habit throughout life.

Dr. Getchell of Worcester referred to a case of foreign body in the antrum consisting of a thickened plug of mucus. This was removed and recovery was satisfactory.

Dr. Coakley of New York referred to the difficulty encountered in the after-treatment of sphenoiditis, especially in keeping the opening patulous. He advocated, where the disease was extensive enough to warrant it, the external operation, where the incision was made alongside the nose, and where the opening could be kept open more easily. With reference to the case reported by Dr. Makuen, Dr Coakley took exception to the curettage of the sinus. He believed drainage should either be restored to a frontal sinus so that Nature could take her course or else that the sinus should be completely obliterated.

Dr. Barnhill of Indianapolis agreed with Dr. Coakley as to the more satisfactory manipulation afforded by the external route in grave cases of sphenoidal disease. He also seconded the remarks regarding curettage of the frontal sinus, believing in the complete obliteration of the sinus, or if drainage was to be secured the inadvisability of curettage.

Dr. J. Price Brown of Toronto mentioned a case of two foreign bodies in the antrum, both consisting of plugs of cotton.

Dr. Sluder of St. Louis added two cases of foreign bodies in the antrum, both consisting of plugs of bismuth paste, one remaining a year and a half, the other two years.

Dr. Myles of New York, in relation to operations on the frontal sinus, said he had always had to remove the nasal processes of the superior maxillary bone, which could only be accomplished with a hammer and chisel. He never curetted the frontal sinus.

Tuesday, May 30—Second Day.

Nasopharyngeal Fibroma.—Dr. D. Bryson Delavan of New York called attention to the fact that, from time immemorial until about thirty years ago, the removal of these peculiar growths had been effected through the performance of some severe preliminary operation by which access was obtained to the affected part. These preliminary operations were of a very serious character, the patient often dying upon the table from hemorrhage or shock or succumbing within a few days. Voltolini of Breslau and Rufus P. Lincoln of New York had deprecated the employment of the preliminary operation and had substituted certain lines of treatment by means of electrical methods. These were used through the natural passages. Thus, the growth was removed bodily by encircling its base with a galvanocaustic loop, causing the loop at a low rate of incandescence to pass through the fibrous tissue. Not only was the danger of severe hemorrhage present in other methods of operating entirely done away with, but the resulting cauterant action destroyed any remnant of the growth to such an extent that in some cases further treatment was unnecessary. In cases where fragments remained these could be eradicated by the direct application of the galvanocautery or by other suitable means. Where a growth was too large to admit of the use of the galvanocaustic loop its volume was first reduced by means of electrolysis or by ignipuncture. Both the unipolar and the bipolar methods of electrolysis were employed, the latter however being preferred. In many cases applications made in this way as near as possible to the base of the growth caused the occlusion of so many of its nutrient vessels that the volume of the tumor was decreased sufficiently to make the use of the incandescent loop practicable. Up to ten years ago a considerable number of successful cases had been reported as cured by this method. During the past ten years it had fallen more or less into disuse, although the statistics which the writer of the paper had taken pains to collect amply proved its vast superiority in point of safety and of efficiency over all other means of treatment. The fact that so many of the leading surgeons of the day gave preference to radical operation made it desirable that the subject should be carefully reviewed; even when the growths were removed through the natural passages by means other than electrical, such as by tearing away of the tumor piecemeal, or its removal by means of the cold wire snare, accidents were common and hemorrhage was almost invariable. In fifteen reported cases treated by electrical methods no cases of hemorrhage, shock, or death were reported, while ten cases were reported as cured, and one improved, the others not having been heard from. As against this through the use of the cold wire snare in ten cases there were reported nine instances of severe hemorrhage and no cases of cure. Of forty-six cases operated upon by severe preliminary operation or by removal piecemeal with the forceps, one death was reported and only five cures. These statistics, covering a period represented by the last ten years, about coincided with those obtained by the writer from the twenty years preceding. They amply sustained the supposition that radical preliminary operation for the removal of fibroma of the nasopharynx was injustifiable; that all of the necessities of the case could be met by means of the employment of electrical methods applied through the natural passages without any preliminary operation whatsoever; that they could be met

by those means without risk to the patient and without resulting deformity, and that the percentage of success through their employment was vastly in excess of that by other means.

Dr. Holmes of Cincinnati called attention to the use of the mercury points either by the unipolar or bipolar method; he stated that with the unipolar 500 to 700 milliampères and by the bipolar up to 2,500 milliampères could be used. He referred to a case of spindle-cell sarcoma involving the tonsil and upper posterior part of the tongue in which he successfully removed the growth; also to a case with involvement of the soft and hard palates; both patients were without recurrences to-day one being of eight and the other of three years' duration.

Dr. Harmon Smith of New York briefly mentioned three cases of postnasal fibroma including the entire posterior nares reduced by the injection of monochloracetic acid; there were no recurrences.

Case of Spindle-Cell Sarcoma of the Larynx Treated by Electrocautery Operations and the Application of Radium.—Dr. J. Price Brown of Toronto reported the case of a young man of 22 suffering from a rapidly growing tumor in the larnyx. Previous to two months before Dr. Brown saw him he had been in excellent health, with no throat symptoms whatever; then for several weeks there was gradually increasing stenosis until the point of suffocation seemed impending. On examination a large, corrugated, dark red growth could be seen through the throat, nearly filling the larynx; it was like a large strawberry, seemed to be very widely sessile in attachment and was located more to the left than to the right side. The glands of the neck on the same side immediately adjacent to the growth were large and somewhat tender. The voice was not much affected. Owing to the size of the tumor and the involvement of the glands of the neck the case did not seem suitable for radical external operation. Accordingly, under cocaine and adrenalin anesthesia the speaker commenced electrocautery operations, first to be able to remove a large segment for microscopical examination, and then for removal of the growth. After several sittings he secured a piece about the size of a marble of solid tissue, removing it by snare for histological examination. Dr. Archibald examined it carefully and pronounced it to be undoubtedly rapid growing spindle-cell sarcoma, occurring in a very unusual situation. Having been able to remove so much by aid of the electrocautery knife, the speaker continued the electrocautery operations daily, the blade being at a white heat In about three weeks the large bulk of the growth had been removed and the speaker concluded to try the effect of the application of radium at the base. Accordingly Dr. Ryerson of Toronto substituted for one week radium applications in place of electrocautery operations The pain seemed to be lessened by the application of the radium; but during the week of its use the growth of the tumor was enormous and the glands increased in size. The larynx was full again, although the new growth was lighter in color and softer. So the use of radium was stopped and a return to electrocautery operations was adopted. For a while the operations were daily; then as the tumor decreased in size they were made on alternate days. At the time of reading the paper the growth had almost entirely disappeared, although certain points still required treatment. When the man first came for operation his weight was 130 pounds; two months later after the many cauterizations he weighed 124 pounds. One month later at the time of reading of the paper it had increased to 139 pounds. The glandular enlargement had disappeared, the larynx was quite open, and the patient was taking his meals regularly with the family at the table. During the early part of the treatment he was fed solely on milk, which he could always swallow well, although it pained his ears while drinking. At no time his food or drink got into his larynx. During all the early operations there was always profuse bleeding, but later there was little or none.

Dr. Mackenzie of Baltimore said that the use of radium in cavities more or less inaccessible, that is, where the operator could not watch the agent every instant during application, was to be deprecated, and that no less an authority than Wickham of Paris had said that under no circumstances should this agent be used in the deep throat cavities, in the larynx, or deep parts of the pharynx. The speaker considered that the *x*-rays had proven quite successful in the pharynx.

Esophagoscopy and Bronchoscopy by the Killian Method.—Dr. Thomas Hubbard of Toledo reported a series of operations for removal of foreign bodies from the esophagus and the bronchi. (1) Boy aged 4. One cent piece in esophagus one month, complicated by stricture due to lye swallowed when two years of age. (2, 3) A group of coin and button cases were briefly referred to. Two cases having fragments of bone impacted in esophagus each five days, operated on by local anesthesia. One fatal case of impacted bone in esophagus one week; death due to pneumonia. (4) Girl aged 3 having a large open safety pin in esophagus. Details of method of turning the pin on the embedded point based on measurements of radiograph to determine the safety of this method. For instance, in the case detailed, the process of turning the pin by traction on the shield by means of a hook stretched the esophagus only one-quarter of an inch more than it was as shown in the radiograph. This was done and no traumatism resulted. A snare was exhibited by means of which an open pin could be closed *in situ*. (5) Brass Christmas tree candle holder removed from the esophagus of an infant of eight months. (6) A series of radiographs of a case having an upholsterer's tack in the left lung for eight years were exhibited, showing disappearance of the shaft and changes in the lungs. (7) Brass ferrule with rubber eraser in one end and a steel pen in the other, removed from the right bronchus. (8) Steel glass-headed pin removed from the left lower lobe bronchus of an infant after one week. (9) Screw bolt removed from right lower lobe bronchus of an infant after five days. (10) Fragment of cement tooth filling, removed from the lower lobe, right lung of a woman, seven months after aspiration. During extraction of teeth this fragment snapped into the trachea. An abscess cavity formed and the fragment was located below the ninth rib near the spinal column and extracted through the Killian tube. A group of cases having kernels of corn, seeds, nutshell fragments, peanuts, etc., operated on in part by the Killian method, were briefly referred to.

Dr. Makuen of Philadelphia referred to a case in which he met with a rather unusual difficulty. In attempting to remove a safety pin by means of the ring instrument, the glottis, sphincter-like, grasped and held the instrument so tightly that it was impossible to extricate it; finally the pin was pulled through the bronchoscope, but fell on the floor before the operator had an opportunity to see how it had been held in the ring.

Dr. Jackson of Pittsburgh considered Dr. Makuen's case a unique one. With regard to esophagoscopy and bronchoscopy he considered it required a great deal of ingenuity and the ability to meet emergencies for these procedures to be safe. He said that in his opinion the removal of an open safety pin was extremely dangerous, and that he considered it a better method to push such a pin down into the stomach, turn it around, and then pull it out, rather than to try to turn it around in an already stretched esophagus. He also mentioned the frequent dyspnea in esophageal cases produced by the depression of

the trachea during an attempt to remove a foreign body from the esophagus; this was frequently apt to end fatally. He laid great stress on the fatal nature of the peanut, stating that in his opinion it was the most serious of all foreign bodies becoming lodged in the bronchi, referring to three personal cases of great interest.

Dr. Mayer of New York stated that he believed the bronchoscope would soon come to fill a rather different field than that used for it to-day, namely the ability by its use in the hands of skilled bronchoscopists of ascertaining the presence of new growths and other conditions in the air passages.

Are Tonsils a Menace or a Protection?—Dr. Henry L. Swain of New Haven discussed the question as answered, first, in the practice of throat surgeons all over the country. As they almost universally were adopting the operation of tonsillectomy whenever they attacked the tonsils, the inference was that the latter were surely of account and always a menace. Answering the question from the anatomical and physiological standpoint, the evidence adduced was such that it could be readily proved that the tonsil was to all intents and purposes a lymphnode and was of just as much importance, no more, no less, as any other node. He called attention to the fact that the tonsils (faucial) had lymphatic trunks leading into them, which drained from the nose and palate, so they had a very definite office in caring for this lymph, a very different viewpoint from the usual one of being a mere retentive area for matter soaking into them from the mouth. Being thus, when in health, an active agent of protection to the system, the tonsil must, like the whole lymphatic system, be of relatively greater importance to the very young child than to the adult. These two facts were strengthened by the additional observation that as the healthy normal individual always had such tissue, which began to functionate early in life in the adenoid tissue in the nasopharynx, in the faucial tonsils in childhood, and in the lingual tonsil in later adult life, it would seem absolutely proved that the body required some such physiological action of some such tissue for its proper development or in its economy, *i.e.* a definite function for lymphoid tissue. Taking this as true, it would be absolutely illogical to remove any of it except for just cause, and this led Dr. Swain to deplore tonsillectomy, complete removal of the tonsils, as an indiscriminate routine procedure in young children, especially when this was accompanied by complete adenoidectomy. The adenoidectomy was to be commended—too thorough an operation was rarely possible—but in early childhood a portion of the healthy faucial tonsil tissue could be well allowed to remain. The system might have need of it. When diseased any of the good operations for tonsillectomy could be used, but he felt that the teaching should be that, even in adults, there were other methods of bringing about a satisfactory and safe condition of the tonsils. These latter he almost universally employed by preference and such patients had, at least, the benefit of whatever protection the saved tissue could be to them.

Dr. George B. Wood of Philadelphia objected to the views held by the essayist, and stated that by repeated experiment he had been able to prove that the lymph flow in the tonsil was an efferent current. If a tubercle bacillus is placed in a crypt of the tonsil it will produce tuberculosis of the tonsil; at almost the same time tuberculosis will start in the lymphnode draining that tonsil. He did not believe it to be possible to tell macroscopically a diseased tonsil. He regarded the function of the tonsil to be primarily concerned with the production and elimination of lymphocytes. He advocated in all diseased conditions the complete removal of the tonsil, having obtained for better results from this procedure than from tonsillotomy.

Dr. J. G. Wilson of Chicago agreed with Dr. Swain that the physiological activity of the tonsil was principally confined to fetal and infant life, but did not consider it as a pure lymphatic gland. He called attention to the fact that in its development as an ingrowth through the second branchial cleft it differed from other lymphnodes, which developed as a breaking up of the lymphatic cords. He said that the rat was the only animal he had found in a study of the comparative anatomy of the tonsil which did not possess this organ.

Dr. W. E. Casselberry of Chicago said he had never seen a particle of detriment to either the child or adult resulting from the total excision of the tonsil, but explained this on the basis that there were supplementary tissues to continue its function. He agreed with the essayist that during childhood the tonsils should never be removed unless definitely diseased, but advocated their absolute removal if operated upon at all.

Dr. Mackenzie of Baltimore emphatically voiced his disapproval of the indiscrimnate removal of tonsils so largely practised at the present time, and considered it the duty of every laryngologist to make the conditions warranting tonsillectomy plain to the general practitioner.

Dr. Coakley of New York called attention to the fact, also referred to by Dr. Swain, that the tonsils in children and in adults were entirely different in function; in adult life it was classed more as a pathological than as a physiological organ. He mentioned the fact that frequently in adults with rheumatic diathesis the removal of the tonsil which had caused quinsy, etc., would show an abeyance of these peculiar manifestations. It was his opinion that tonsils should be enucleated and not cut off, and his experience had been that the children in whom this procedure had been carried out because of disease of the tonsils as a general rule became markedly improved in health following the operation.

Dr. Coolidge of Boston discussed the etiology of acute tonsillitis, referring to the recent epidemic in Boston, which was at first traced to the milk supply, but later became general throughout the city. He considered in view of the mode of onset that the condition in the tonsil pointed rather to an efferent than to an afferent flow of the septic microorganisms or their toxins.

Dr. Coffin of New York called attention to the frequency with which tonsils which macroscopically appeared unaffected were found microscopically to be diseased. He considered the most dangerous of all tonsils to be those stumps remaining after a tonsillotomy and urged the total excision of the tonsil.

Dr. B. R. Shurly of Detroit deprecated the removal of tonsils unless proved to be diseased. In many hundreds of tonsillectomies he had seen nothing but favorable results. He believed children whose tonsils had been removed were less liable to the various throat complications if they became the victims of the infectious diseases of childhood.

Dr. Bliss of Philadelphia also considered the stumps of tonsils remaining after partial removal to be a great menace to the health of the individual. He made a plea for the school children now being sent to the various dispensaries for treatment, urging that wherever indicated the tonsils should be removed, but where there was no absolute indication for this procedure that the laryngologist should refuse to consider operation.

Wednesday, May 31—Third Day

The Technique of Tonsillectomy.—Dr. J. M. Ingersoll of Cleveland gave the following as the method of tonsillectomy used at the dispensary of the Lakeside Hospital: Ether was used for the anesthetic in adults as well as in children. The patient was operated upon lying on the back with the head over the end of the table. One assistant sat on the left and held the patient's head firmly with both hands. The second assistant stood on the right

and held the tongue depressor with his left hand and sponges with the right. The operator sat at the end of the table with the patient directly in front of him. One tonsil was grasped with a pair of forceps and pulled toward the median line, and the mucous membrane was carefully incised down to the capsule of the tonsil. The tonsil was then carefully dissected free with its capsule from the anterior and posterior pillars, and from its attachment superiorly and somewhat inferiorly. The enucleation was completed with the snare. A gauze sponge was then packed into the fossa and held in position for two or three minutes with firm pressure. This pressure usually stopped the bleeding. If the bleeding continued the bleeding points were grasped with ordinary hemostats and twisted. If an artery large enough to spurt had been cut, it was grasped and a buried catgut ligature passed around it and tied tightly. The second tonsil was then operated on in the same way, and when all hemorrhage had been controlled an adenotomy was done if necessary.

Relation of the Tonsil Operation to the Soft Palate and Voice.—Dr. G. Hudson Makuen of Philadelphia stated that the purpose of his paper was to discuss the causes leading to the popular belief that the removal of the tonsils injured the voice. There was no absolute standard of vocal excellence and the voice which sounded good to one might sound very differently to another. This fact accounted for the great difference of opinion now prevailing as to the effect of the tonsil operation upon the voice. The three important vocal organs considered in this connection were the soft palate, the tongue, and larynx. The soft palate was especially affected by the tonsils, and it was one of the most important of the phonatory organs, because upon its normal action the normal action of all the others depended. It had two important functions in phonation, one being a valvular function by which vocal resonance was markedly affected, and the other had been called a thyroid-tilting and cord-stretching function by which the quality and pitch of the voice were determined and regulated. This valvular action of the soft palate might be greatly interfered with by abnormally large or degenerate faucial tonsils, the large ones interfering with the motility of the depressor muscles, and the degenerate ones having somewhat the same effect by the catarrhal hypertrophies and adhesions which they engendered. Moreover, when the valve failed to close and the soft palate being limp in the oropharynx, the palatopharyngii muscles, having lost their anchorage in the vault, were quite unable to perform their thyroid-tilting and cord-stretching function, and the voice necessarily suffered as a consequence both in respect to quality and to pitch. The normal tonsil, serving as it did to keep the faucial pillars apart and thus determining to some extent, at least, the direction of their forces in the act of phonation, must be beneficial to the voice rather than otherwise, and its presence might also improve the resonant quality of the voice. There were two types of abnormal tonsils, the simple hypertrophied and the degenerate types, and both types interfered with the valvular action of the soft palate, thus impairing directly the resonance of the voice, and, indirectly, its quality and pitch. A tonsil operation under these conditions was absolutely imperative in order to improve or save the voice, as well as to remove sources of general infection. The operation which should be chosen is the one that would best remove foci of infection and at the same time conserve the phonatory and articulatory functions of the neighboring organs. While complete tonsillectomy best fulfilled the first of these two indications, it might not be the operation best adapted to the conservation of the functions of the neighboring organs, because, however well it might be done, it resulted in cicatricial contractions and adhesions in the tonsillar fossæ, which interfered with the functions of the surrounding muscles. When, therefore, the capsule was not hypertrophied and no inflammatory adhesions existed between it and the surrounding muscles, one should probably get better results so far as the phonatory functions of the palate were concerned by removing the tonsil only and leaving the capsule intact. This, of course, was the more tedious and difficult operation, and in some instances it might be an almost impossible one, but nevertheless in selected cases the procedure should be at least attempted, because it left the palate in a better functional condition. Every case should be a study in itself, and in all cases it should be a question of judgment with the operator as to whether a complete tonsillectomy should be performed or an attempt made to do an extracapsular operation by some of the many methods which had been devised. As in so many other instances, the mistake was often made in supposing that a single operation was suitable in all cases, and one was not sufficiently governed in one's choice of methods by the conditions as they presented themselves. The sacrifice of one or more pillars of the palate should give one great concern, because the results upon the voice and speech had been in some cases not only disastrous but altogether irreparable.

The Relation of Enlarged Tonsils to Endocarditis.—Dr. Albert C. Getchell of Worcester, Mass., stated that of late years there had been a growing tendency to ascribe constitutional diseases, among them endocarditis, to enlarged tonsils. With the interest in the operation for a complete removal of the tonsils, this question took a practical as well as a theoretical turn. A review of the literature on diseases of the heart and diseases of children showed in general a cautious acceptance of this view. Some authors, however, stoutly maintained it, while others did not discuss it. The writer's clinical experience showed that evidence of endocarditis was not commonly found in patients who came for removal of tonsils, and he concluded from a study of the subject that enlarged tonsils in themselves did not contain the foci of disease that produced endocarditis. Therefore, the operation for their removal should not be unduly difficult nor dangerous.

Primary Chancre of the Tonsil.—Dr. A. B. Thrasher of Cincinnati stated that syphilis must no longer be regarded as a venereal disease. It was especially with reference to chancre of the tonsil that this was true. A singular thing was the diversity of views in reference to the comparative frequency of chancre of the tonsil. When one considered extragenital chancre the relative frequency of tonsillar lesions varied according to the different observers from 1 to 75 per cent.; also in reference to the real frequency of tonsillar chancre. Sabolotsky reported the observation of 104 tonsillar chancres in one year, while on the other hand Protzeck saw but one case in twelve years. By far the most frequent cause of tonsillar infection was the virus conveyed by kissing. Three out of the four cases falling under the observation of the writer were caused in this way. Infection had occurred from eating utensils, drinking vessels, from pipes and cigars (the cigar maker moistening the wrapper with luetic saliva), lead pencils, nails, tooth brushes, etc. The most subjective symptom has been pain in the region of the tonsil markedly more prominent than in other diseases of this region. There was no special difficulty in differential diagnosis except possibly from cancer or from tubercle or syphilis mixed. For cancer of the tonsil it was sometimes necessary to resort to the microscope and serum test to establish the diagnosis. The disease spread more rapidly when introduced through the tonsil than through any other region of the body, and secondary symptoms were usually present when the primary lesion was first discovered. However, in the early stages of tonsillar in-

fection the serum diagnosis had not proven reliable, probably because the virus had not extended into the system from the encapsulated tonsil. The treatment was not different from that of other primary lesions. Should one, however, discover the contagion of a tonsillar infection when there was a possibility that general infection had not occurred, immediate tonsillectomy might be made with a faint hope of eradicating the local poison.

Late Secondary Hemorrhage Following Tonsillotomy.—Dr. Frederic E. Hopkins of Springfield, Mass., reported this accident occurring in a child of nine and in a young man of 19. In one case severe hemorrhages occurred as late as the eleventh day; in the other as late as the twelfth day.

Dr. Wood of Philadelphia mentioned a case of late hemorrhage following seven days after operation for adenoids, being so severe as to require etherization and packing of the vault.

Dr. Richards of Fall River added to the list two cases of late hemorrhage, occurring in one case five days after operation, in the other six days after operation. He also mentioned a fatal case of late hemorrhage following an adenoidectomy. In discussion of Dr. Makuen's paper he took exception to the author's statement that because there was a large hole on one side of the palate and not on the other side it was indicative of a poor operation, for sometimes the supratonsillar fossa was higher on one side than on the other.

Dr. Casselberry of Chicago referred to the cause of late hemorrhage, and stated that in almost every case it was due to the separation of a slough, the result of the operation. He advocated the use of the clamp under these circumstances, having always had very good results from its use; and also mentioned that in operations in his office upon adults, if hemorrhage occurred, he immediately applied the galvanocautery to the bleeding point, and had found this measure most efficient in controlling the bleeding.

Dr. Richardson of Washington, D. C., stated that many times cases were referred to the specialist by the general practitioner for removal of tuberculous or otherwise diseased tonsils, when the specialist could find no evidence of any disease, and he considered that the time had come to refuse to operate on any tonsil until it could be proven microscopically, or possibly macroscopically in some instances, to be diseased. He referred to the many complications which followed tonsillectomies, viz., emphysema, pneumonia, and pleurisy, mentioning one case of a child in which the latter condition developed and ended fatally.

Dr. Kyle of Philadelphia advocated, in cases of enlarged tonsils when the patient was otherwise healthy and no definite disease of the organ could be demonstrated, the loosening of the tonsil from the existing adhesions, without cutting the connective tissue in the soft palate or the anterior or posterior pillars; he reported satisfactory results after this procedure. In making a diagnosis with regard to the tonsil he urged that the operator should satisfy himself that the condition was not the result of some systemic upset before performing a a tonsillectomy. He considered that the size of the tonsil had little to do with its dangers, as a small tonsil could be just as great a menace at times as an enlarged one. In discussion of Dr. Makuen's paper he mentioned the fact that in irregularities of the palate the individual adapted himself to the condition by twisting his mouth in usch a way as to overcome the liability of making a false sound, and said he had frequently noticed this in singers.

Dr. Coolidge of Boston, in discussing Dr. Thrasher's paper, reported briefly a case of primary chancre of the tonsil in which treatment with 606 was begun just as the secondary manifestations began to appear. The chancre disappeared rapidly and the secondary eruption also disappeared, and in a week or so the patient seemed fully recovered. With regard to the question of tonsils, he believed that it was unfair to the specialist for the general practitioner to expect him to make a diagnosis from the appearances of the tonsil alone, but that he should always insist upon hearing the whole history before giving his ultimatum.

Dr. Delevan of New York referred to the fact that the removal of the tonsils was probably one of the earliest operations known to man, and the fact that for many generations it was abandoned rather pointed to the belief that there must have been some good cause for this step, and he urged caution in returning to tonsillectomy as a routine practice, considering that each individual case required separate steady. He condemned the practice, which he stated to be quite prevalent, of practitioners in other lines of work, such as gynecology and pediatrics, undertaking the removal of tonsils.

The Effect of the Cautery on Tuberculous Lesions.—Dr. George B. Wood of Philadelphia stated that clinical experience and experimentation on guinea-pigs showed that the cautery was an almost ideal method of treating localized tuberculosis. It was shown that there existed a retarding influence on the spread of the disease beyond the area actually destroyed by the heat. Within three days a marked zone of inflammatory reaction was found just outside of the cauterized area and in this zone an excessive amount of fibrous tissue developed. The development of this fibrous tissue had a marked influence on the limiting of the tuberculous disease. Formation of new blood-vessels in the inflammatory zone brought sufficient nutrition to the part to keep it from breaking down and becoming necrotic, while the eschar produced by the burning prevented reinoculation and sealed the lymphatics and blood-vessels.

Dr. Getchell of Worcester, Mass., considered that if the constitutional disease was active the local treatment should be of the mildest nature, but if the constitutional treatment was in abeyance and the general condition of the patient good, while the local lesion was of a sluggish character, stimulating treatment was a proper procedure

Dr. Richards of Fall River stated that at first he had held the opinion voiced by Dr. Getchell, but to his surprise the reaction after the electric treatment in these cases was much less than that following other methods, while the results were much more rapid and satisfactory.

Congenital Web of the Esophagus: Report of a Case.—Dr. J. Payson Clark of Boston reported the following case: A woman, aged 24, had always been obliged to mince her food in order to swallow it. There was no history of trauma. A year before he saw her she had had a choking attack following an attempt to swallow a piece of meat. Since then she could swallow only liquids. She was well developed and nourished. Attempts to pass bougies failed. Under ether anesthesia examination with Jackson's tube spatula revealed a membrane shutting off the esophagus from the pharynx except for an opening 3 to 5 mm. in diameter. On attempting to place this membrane on the stretch with an esophagoscope it gave way and the instrument passed on to the stomach without meeting further abnormality. The patient had no further difficulty in swallowing. This case was apparently unique as no report of a similar one could be found in the literature.

Dr. Mosher of Boston reported a case of complete web of the esophagus, in which examination showed a thin diaphragm at the upper end of the esophagus; after evulsion of the same the symptoms, which had persisted for fifteen years, disappeared. He considered that probably on careful examination it would be found that many cases attributed to nervous affections were in reality the

result of slight webs in the upper part of the esophagus.

Dr. Swain of New Haven referred to a case which he believed to be of this variety, but in which the patient passed from under his care before a definite diagnosis could be made.

Election of Officers.—The election of officers for the coming year resulted as follows: *President*, Dr. James E. Newcomb, New York City; *First Vice-President*, Dr. Frederic C. Cobb, Boston, Mass.; *Second Vice-President*, Dr. Burt R. Shurly, Detroit, Mich.; *Secretary and Treasurer*, Dr. Harmon Smith, New York City; *Librarian*, Dr. Joseph H. Bryan, Washington, D. C.; *Member of Council*, to serve for four years, Dr. D. Braden Kyle, Philadelphia; *Delegate* to the Triennial Congress at Washington, Dr. William K. Simpson, New York City; *Alternate*, Dr. Joseph H. Bryan, Washington, D. C.

AMERICAN ACADEMY OF MEDICINE.

Thirty-sixth Annual Meeting, Held at Los Angeles, California, June 23-26, 1911.

Friday, June 23—First Day.

A preliminary popular meeting was held at 8 p. m. in the Arrow Theater, with the President, Dr. Charles Stuart Sheldon, presiding. Dr. Donly C. Hawley took the chair and Dr. Sheldon delivered the President's address.

The Latest Improvement in Medical Education.—Prevention.—Dr. Sheldon referred to the desirability of the establishment of a National Department of Health, reviewed the work in the Canal Zone carried on by Colonel Gorgas, and called attention to the results in the fight against malaria, typhoid fever, and tuberculosis. The study of the prevention of infant mortality was mentioned as a field in which until recently little thorough work had been done. To Dr. Helen C. Putnam he gave much credit for aggressive work in this line. The economic protection of the mother was shown to be of great importance since industrial conditions were factors in infant mortality. Compulsory medical school inspection and adequate playgrounds were favored. The speaker pointed out the intimate relation which the medical profession bore to public health.

Eugenics—The Science of Improving the Human Race by Better Parentage.—Dr. Henry B. Ward of Urbana, Ill., said that the determining factor in human evolution was to be found in the blood rather than in external conditions. Investigations showed that the classes of our population characterized by their effectiveness were not maintaining their present numbers, while the most undesirable classes, including defectives and degenerates, had markedly increased in the last fifty years. It was the purpose of eugenics to point out means by which the unfit may be eliminated. While in some States the propagation of criminals and degenerates was limited, Dr. Ward believed that marriage must be safeguarded by legislation regarding permits.

Saturday, June 24—Second Day.

Report of the Committee to Investigate the Teaching of Hygiene in Public Schools.—Dr. Helen C. Putnam of Rhode Island, Chairman of this Committee, reported that the year's study had been concentrated upon the following subjects: healthy parents, right customs and wholesome environment being essential factors in preventing infant mortality; the preparation of teachers to establish through the schools, better practices in hygiene and sanitation and more ideal parenthood. In the schools visited, there was need for standardization. The subject of the training and testing of janitors in sanitary care of school premises had been presented by the speaker before the National Education Association, under the title "Practical Applications of Biologic Science in School Administration." As a result a special committee had been appointed and had arranged a program on "Clean Schoolhouses" for the meeting in the present month in San Francisco. Matters under discussion were said to be methods of training and examining janitors in sanitary care of school premises, with a report of one existing course for janitors. Prosecutions of city governments for injury of children's health by unsanitary schools were said to have already occurred and it was suggested that these seemed as logical as similar action for accidents due to other municipal mismanagement.

Dr. C. D. Lockwood of Pasadena asked how Dr. Putnam would make the ideas suggested effective, and stated that in their own school board the county medical society had been requested to appoint a committee of five, to be known as the Sanitary Committee, its function being to cooperate with the Board of Education.

Dr. Andrew Stewart Lobingier of Los Angeles inquired whether the work might not be carried on under Civil Service direction.

Dr. Lockwood felt that a public sentiment must be created.

Dr. Albert Goldspohn of Chicago spoke of the necessity of the medical profession standing together upon legislative matters, no matter what their school.

Dr. Ray Lyman Wilbur of Palo Alto felt that many of the present hygienic rules were in reality decidedly antiquated and that a perfectly clear understanding of the present day rules was necessary.

Dr. F. M. Pottenger of Monrovia observed that doctors were about the poorest hygienists in the world.

Dr. Putnam in closing, said that while Civil Service was a step in the right direction, it was as yet of little value in the instances in which it was established. She referred to the claim made, that until parents prosecuted school authorities for injury to their children's health schools would not be what they ought to be.

Report of Committee for Teaching Preventive Medicine in Universities and Normal Schools.—Dr. Henry B. Hemenway of Evanston, Ill., presented this report which was read by Dr. McIntire. It was stated that while the importance of hygiene seemed to be fully recognized the responsibility was not always so clear in the minds of those in charge of school curricula. Preventive medicine he had found was not taught in the majority of medical schools. The present backwardness of legislation he attributed in a measure to the ignorance of legislators who had been taught in public schools. He thought it probable that the best mode of instruction would be that of a lecture course open to the entire student body.

Professor Henry B. Ward, Professor of Zoology, University of Illinois, attributed the neglect of this work to the absence of an organized plan, and the lack of demand for such a course. Reference was made incidentally to a textbook which had been prepared by Dr. Andrew Stewart Lobingier, a Fellow of the Academy, as a step in the right direction.

Dr. Edward Jackson of Denver said that in the University of Colorado a course in preventive medicine had been given and was well attended. With Dr. Ward he believed that universities could not be expected to display much interest until something definite had been presented.

Dr. Helen C. Putnam thought that possibly the demand for the teaching of hygiene in colleges and universities might be larger than generally supposed, since at the National Congress on School Hygiene, a resolution had been passed requesting universities and colleges to give such instruction and to require an examination in their entrance test. At the International Congress on Tuberculosis also a demand had been made that universities and colleges should prepare teachers for the public schools.

Report of the Seventh Annual Conference of the Council on Medical Education of the American Medical Association.—Dr. John L. Heffron presented this report which was read by Dr. McIntire. Reference was made to the general recognition that the standard long holding in European medical schools was one for which our civilization was now ready. That the control of medical education should be handed over to the State, as favored by some, did not seem to the writer desirable. So long as medicine was not an exact science, so long would dogmas arise.

Report of the Delegates to the Meeting of the Association of American Medical Colleges.—This report was prepared by Dr. Frederic Gerrish of Portland, Me., and read by Dr. James H. McBride. The writer said that his report was rather one of comment and review since the transactions of the association had already appeared in the journals. That it was wise to insist upon as rigid an apportionment of time as indicated in the curriculum was not clear. It was well known that two of the great schools paid no particular heed to the association's prescription, but since they were "valuable show pieces in the membership list" they were not disciplined. The movement for "whole-time" teachers had been aggressive, indeed to the extent of "ultramodernity," it would seem. That good might come from the proposed coöperation of the Association of American Medical Colleges, the Council on Medical Education, and the Confederations of State Boards of Registration of Physicians was clear to the writer, but doubt was expressed as to the wholesomeness of a combination of those bodies with the Carnegie Foundation, since its work hitherto had not been so clearly permeated with intelligence and actuated by a spirit of fairness as to awaken confidence in its future results.

Dr. Andrew Stewart Lobingier hoped that Dr. Gerrish's criticism of the Carnegie Foundation would not be understood as an expression of the opinion of the Academy.

Dr. Edward Jackson felt that the report was plainly understood to be individual and in no sense the report of the Academy. Admitting that the Flexner report might not be ideal he regarded it nevertheless as an exposure of the weak places in medical education in America likely to be highly beneficent in results.

Should One Expect More Than Mediocrity from the Medical Profession?—Dr. Francis M. Pottenger of Monrovia, Cal., read this paper. The author stated that while all professions and branches of business had their leaders and geniuses, it must be remembered that the great majority followed the leaders at a great distance. The author stated that the one thing which American physicians lacked in comparison with their English colleagues was a good preliminary training, not only in the branches underlying the foundation of medicine but in the foundation of medicine itself. No matter how high the entrance requirements, or how stringent the final examinations, many men, doomed to be failures in their chosen profession, would find their way into the ranks of medicine.

Dr. Donly C. Hawley of Burlington, Vt., said he believed the great majority of men entering the medical profession would render service of about the medium grade.

Dr. Boardman Reed felt that a man might be mediocre in one thing and quite gifted in another.

Dr. L. A. Carter emphasized the importance of the teaching of medical ethics in the medical colleges and emphasized the need of the young physician feeling the responsibility he assumed in taking up his profession.

Report of the Committee on Publishing Details of Suicides in the Public Press.—Dr. Henry B. Hemenway of Evanston, Ill., made this report which was read by Dr. Stuever. The statement was made that newspaper men claimed that it was the province of the papers to publish the news. The committee found that while alienists were practically unanimous in the opinion that the suggestive effect of the reading of details of suicides was a powerful causative factor in suicide among susceptible individuals, yet attempts at legislation were practically useless without a demand by the public. It was found that for each sex, occupations requiring physical activity were less prone to the act except in the case of soldiers and sailors. The writer suggested the advisability of confining pernicious news to a separate sheet of distinctly yellow color. A statistical study showed a continual increase in the death rate from suicide aggregating 60 per cent. in the nine years ending 1908. Not only was there this increase, but death by suicide constituted 1.2 per cent. of all deaths reported in 1909. Nationality had a bearing and geographically the crime was not uniformly distributed.

Neurotic Books and Newspapers as Factors in the Mortality of Suicide and Crime.—Dr. Edward Bunnell Phelps, editor of the *American Underwriter*, contributed a paper upon this topic which was read by Dr. Edward Jackson. Reference was made to the opinion of Dr. William Farr, the founder of vital statistics, that "some plan of discontinuing, by common consent, murder and bloodshed in the newspapers was well worthy the attention of their editors." Tabulations and specific illustrations of the suggestive influence of the press on suicide and crime were given.

The Press and Crimes Against the Person.—Frances Fenton, Ph.D., of Mt. Holyoke College, prepared this paper which was read by Dr. S. C. Buck of Grinnell, Iowa. It was claimed that the extent to which crimes against the person were due to suggestion from the press while not accurately measureable was indicated by the large percentage of published matter dealing with crime. Representative cases were given in which the matter contained in the newspapers was known to have incited to crime. The average percentage of news alone which, in the writer's opinion, should be withdrawn from the columns upon which she based her study was 23.02 for the highest and 7.94 for the lowest. The threat of the press to make the Church bill a dead letter should it become a law indicated the necessity of having judges of high quality and an educated public.

The Newspapers and Crime.—Dr. William S. Wadsworth of Philadelphia contributed this paper (by invitation) which was read by Dr. C. L. Lowman of Los Angeles. The author expressed his conviction that newspaper accounts of crime did have a pronounced influence upon the readers and instanced an epidemic of cyanide poisoning which was predicted to result from newspaper accounts that had appeared of a crime committed recently. A plea was made for the protection of those accidentally potential and the congenitally defective.

Sunday, June 25—Third Day.

Dr. L. Duncan Bulkley of New York in the Chair.

A conference was held in the First Methodist Church.

The Effect of the Medical Missionary on the "Sociology" of the Orient.

Present Magnitude of Altruistic Medical Effort in the Far Orient.—Dr. Charles McIntire of Easton presented this paper comparing the beginning of medical missions in China with the reports submitted to the Edinburgh Conference last year. Dr. Peter Parker in 1835 had opened an ohpthalmic hospital in Canton, securing the following day one patient. The Edinburgh reports showed that there were now 207 hospitals in China that treated 58,757 in-patients for the year. The study also showed that in Korea, Japan, the Chinese Empire, Siam and French Indo-China, the Dutch East Indies and India there were 716 missionary physicians, 410 hospitals, and 681 dispensaries. The work was regarded as claiming the in-

telligent and sympathetic coöperation of the profession at home.

The Medical Uplift in Burma.—Dr. ELMER S. CORSON of Bridgeton, N. J., formerly of Toungoo, Burma, contributed this paper which was also read by Dr McIntire. The paper stated that while the British Government, so far as her dependencies were concerned, had an efficient medical service in all centers of population, yet the vast agrarian population was practically without medical aid. Every large mission was said to maintain a large central boarding school. The mission school hospital in which those desiring might add a knowledge of medicine during their regular schooling was regarded as the main means at present for solving this vast problem. Socially the practical knowledge of medicine, though given in a desultory manner, had conferred incalculable benefits.

The Caroline A. Ladd Hospital, Presbyterian Mission, Pyengyang, Korea.—JAMES HUNTER WELLS, Surgeon in charge, and formerly of Portland, Ore., made this contribution. The paper was read by the President, Dr. Sheldon, and described the conditions at Pyengyang sixteen years ago at the time the author reached that city. He found a city of 50,000 people entirely without any scientific surgical aid. Some. of the Chinese methods in use at that time included the use of fat to increase one's weight, the use of deer bones to make legs that were stiff with rheumatism, agile like those of the deer. He had about a thousand patients a month. Tribute was paid to the splendid work of the Japanese in their handling of epidemic cases.

Necessity for Trained Workers.—Dr. MARY ELSIE CARELTON of Ming Chiang, China, Physician in Charge of the Dr. Nathan Silas Memorial Good Shepherd Hospital, in a paper read by Dr. Herbert E. House of the Canton Christian College, made a plea for a body of trained, qualified medical men and women. She stated that the only solution of the problem lay in medical colleges and nurses' training schools in China. The ideal was contemplated in the suggestion of the possibility of medical colleges in the United States offering free scholarships to Chinese boys and girls, or of groups of physicians assuming the support of a Chinese student in one of the medical institutions in China and the question was raised whether a nobler gift could be made than to return to these awakened needy people every eight or ten years one of their own people thoroughly prepared to enter the profession of medicine.

The Education of the Chinese in Western Medicine.—Dr. H. H. BOYD told of the need of sanitation in China and of the effort to fight the tuberculosis scourge there. Further, he outlined the work which was being done for the insane and the blind.

Monday, June 26—Third Day.

Contagious Diseases in Schools.—Dr. ERNEST BRYANT HOAG of Berkeley, Cal., in presenting this paper, which was read by Dr. Donly C. Hawley, outlined the work done at Berkeley in the prevention of contagious diseases The paper particularly emphasized the importance of accurately collecting data and exhibiting them as far as possible in a graphic form by means of charts and the plotting of curves.

Dr. HELEN C. PUTNAM referred to the common drinking cup as one of the readiest means of contagion. She felt it imperative that with compulsory school laws the utmost care must be taken to prevent injury to the health of the children by the room environment. Reference was made to legal action in a case in which the parents had no difficulty in proving to the court that the children's health had been injured by the unsanitary condition of the school.

Leartus Connor: An Appreciation.—Dr. JUSTIN E. EMERSON of Detroit presented this paper, which was read by Dr. Charles McIntire.

Monday, June 26—Fourth Day

Should There Be Two Degrees in Medicine? Memoranda in Absentia.—Dr. HELEN C. PUTNAM had addressed a number of educators upon this subject and read the replies, some of which favored a second degree and some not.

The Need of More Than One Degree in Medicine.—Dr. BOARDMAN REED in presenting this paper expressed his conviction that if the laity were better instructed in the elementary principles of hygiene and medicine, they would insist upon higher standards, and that if the medical colleges would maintain as high standards as was right, the establishment of one or two more degrees in medicine would promise well.

Should There Be Two Degrees in Medicine?—Dr. RAY LYMAN WILBUR, of the Department of Medicine, Stanford University, expressed the belief that efforts should be made to cause the medical degree to have a uniform and recognized merit. The givinig of a degree for rsearch work done after the attainment of a properly grounded medical education, however, was to be considered. The only proper basis for granting such degree should be high and uniform standards. The suggestion that if the academic yearning for labels were so strong that there must be a degree and a specially lined and colored and shaped gown and hood accompanying it, then it should be made a degree of real individuality, and based upon two years of fruitful research work done after the properly given doctor of medicine in some institution of learning.

Postgraduate Degrees in Medicine.—Dr. ANDREW STEWART LOBINGIER of Los Angeles said there must be entire reconstruction of undergraduate schools of medicine before there could be established effective postgraduate courses of medical study. The first efforts, he felt, should be directed to reducing the number of schools to one-tenth the present number. He regarded it as more consistent with the accredited value of these degrees if the bachelor's degree were granted in the undergraduate course and the doctorate in medicine granted for the completion of a course of postgraduate work leading up to the ultimate qualifications for the various specialties. If possible after taking his postgraduate degree, which should be a doctorate in his specialty, the student should spend two or three years at least as assistant to a master surgeon or other specialist before being licensed to practice his specialty.

Dr. CHARLES LYMAN GREENE of St. Paul regarded the adoption of the English system of giving a bachelor degree absolutely impractical in this country. The mistake had been made primarily in granting the doctor's degree which was not justified and now an attempt should be made to build up the schools to make good the bestowal of a M.D. degree. Postgraduate degrees, he believed, would come after the medical schools had been improved.

Dr. ARTHUR E. HERTZLER, Kansas City, felt that an urgent step was to eliminate the pseudo-specialist.

Dr. CHARLES D. LOCKWOOD said that the present course in the average medical school could not adequately develop the research worker. For him there should be special schools for this development. He felt that the good general practitioner was the product most needed.

Amendment of Constitution.—The Constitution of the Academy was amended so that hereafter the qualifications for membership shall be: "The Fellows shall be liberally educated physicians as interpreted by the rules formulated by the Council and adopted by the Academy."

Sixteen names were added to the Fellowship List.

Election of Officers.—The following officers were elected: *President*, Dr. Alexander R. Craig, Chicago, Ill.;

Secretary, Dr. Charles McIntire, Easton; First *Vice-President,* Dr. W. Blair Stuart, Atlantic City; *Second Vice-President,* Dr. Albert Goldspohn, Chicago; *Third Vice-President,* Dr. Ray Lyman Wilbur, Palto Alto; *Fourth Vice-President,* Dr. Arthur E. Hertzler, Kansas City.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held May 16, 1911.

DR. H. S. PATTERSON IN THE CHAIR.

THE evening was devoted to contributions from the medical wards and pathological laboratories of St. Luke's Hospital.

Further Reports on the Treatment of Typhoid Fever with Vaccine.—Dr. AUSTIN W. HOLLIS made this report. He said that last year he had reported eleven cases of typhoid fever treated at St. Luke's Hospital with vaccine, and compared these with a number treated during the same season with hydrotherapy. Aside from a larger number of relapses these cases presented a highly encouraging comparison. The present report comprised 40 cases which Dr. Hollis had observed during his service at St. Luke's. The average duration of the fever in the series was thirty-two days. Relapses occurred in 12 per cent. of the cases. Two cases died, making the mortality 5 per cent. The Widal reaction was positive in 90 per cent., and the blood culture was positive in 32 per cent. There were no hemorrhages, no complications and no perforations, except one case of phlebitis. The two fatal cases were beyond medical aid when admitted and received only a few doses of vaccine. They had used the same method that was used in the cases last year. The initial dose of fifty million dead typhoid bacilli was given as early as possible and repeated every other day. In the majority of cases as soon as the temperature showed a lower average the dose was increased by fifty million at each injection. The injection was given in the back of the upper arm; as a rule smarting followed the injection. Often there was a slight swelling or erythema but no marked local reaction. There never appeared to be any constitutional reaction. The proof of the mode of action of the bacterial vaccines in increasing the opsonins causing phagocytosis had been demonstrated by Sir A. E. Wright, who first proposed their use in the treatment of disease. During the course of their use in typhoid fever they had obtained evidence of markedly increased agglutination as shown by the Widal reaction. In one case the administration of typhoid vaccine after a fever lasting sixty-seven days was followed by the appearance of the Widal reaction. In a case of Hodgkin's disease with long-continued fever and no sign but a moderately enlarged spleen, after using typhoid vaccine the blood showed a positive Widal reaction. As a rule a pronounced fall in temperature was seldom seen sooner than one week after the use of the vaccine although it was very common to note a moderate drop in temperature within forty-eight hours after its injection. The series of cases showed nothing very striking in the duration of the fever but the low mortality and absence of complications, especially hemorrhages, encouraged them to continue this treatment. The mortality of typhoid fever in the New York Hospitals was generally over 10 per cent. Dr. James G. Callison reported 303 cases before the Medical Association of the Greater City of New York at the meeting on May 15 with a mortality of 5 per cent. and 5½ per cent. relapsed. The medical profession had been most faithful to the Brand method, but after twenty years' experience with it Dr. Hollis said he would be glad to give it up. The injections of vaccine were continued for ten days after the temperature had become normal. He did not use a larger dose than fifty million and if the fever continued over twenty-five days he advised dropping the vaccine if it had been used early in the disease.

Dr. ALFRED MEYER asked Dr. Hollis the number of cases that had been treated with vaccines.

Dr. HOLLIS replied that during the past year eleven cases of typhoid fever had been treated and without a death. His present report comprised forty cases with a mortality of 5 per cent.

Dr. ALFRED MEYER thought that it might be interesting for the members of the Section to know that at Mt. Sinai Hospital a committee had been appointed to consider the question of the feasibility of introducing this method of immunization. No suggestion had been made as to the duration or the extent of the immunization. It was also interesting to note that one of the workers in the laboratory accidentally sucked up with a pipette living typhoid bacteria. Various remedies were employed including lemon juice. Five hundred million of dead typhoid bacilli were used, but the patient developed typhoid afterwards. He belonged to a family who were prone to this disease.

An Unusual Case of Intermittent Febrile Hodgkin's Disease.—Dr. HOLLIS reported this case. The patient, a man thirty-one years of age, entered St. Luke's Hospital September 5, 1910, with a history of fever and progressive loss of flesh and strength extending over a period of one year. It was supposed that he had incipient tuberculosis and he had spent a part of the year at Loomis Sanatorium. He was a civil engineer and had been in this part of the country mostly in wet swampy districts. He took a glass of beer occasionally and had smoked to excess before the onset of his illness. At the time of his admission he was moderately prostrated and markedly emaciated. The heart appeared normal in size at the apex, and over the pulmonic area there was a soft systolic murmur. The action was regular, rapid, and forcible. The lungs showed moderate dullness at both apices. At the right apex, just below the spine of the scapula, were a few subcrepitant râles. The abdomen was scaphoid; the spleen descended about two fingers below the free border on inspiration. The right kidney could easily be felt. The temperature ranged between 102° and 104.8° F., the pulse was about one hundred, and respirations twenty to thirty-two. The blood count showed 3,300,000 red blood cells, with 35 per cent. hemoglobin; white blood cells, 3400; polymorphonuclears 46 per cent., and leucocytes 54 per cent. The blood count taken a short time after admission showed what appeared to be a short-chained streptococcus, and from this an autogenous vaccine was prepared and the patient received increasing doses with what appeared to be excellent results. His temperature came down and remained there for three weeks, when without any apparent cause it jumped to 103° and thereafter remained above normal, ranging between 100° and 104°. The course of the disease was uneventful and marked only by progressive asthenia, anemia, and emaciation, finally ending fatally three and one-half months after admission. While the present case was under observation for only a part of the course of the disease, there were apparently three periods of pyrexia, and two of apyrexia, the first of about a month, the second lasting almost three weeks. The second unusual phase of this case was the distribution of the glandular involvement. At no time in the course of the disease was there any enlargement of lymph nodes palpable, and at no time was there any enlargement of the deeper nodes, either by direct evidence, or by secondary pressure signs. There was no sign of any pressure on any nerve or upon the larynx, trachea, bronchi, or esophagus, nor was there any dyspnea or dysphagia. There was never any edema nor was there evidence of ascites. There had been cases of Hodgkin's reported in which the deep glands were the only ones involved, but they seemed quite regularly, especially in the later stages of the disease, to have given secondary

signs of pressure. The blood findings were interesting in that in spite of fever there was a gain in red blood cells and hemoglobin. The digestive ability was always good. Leukopenia was a marked and constant feature, the leucocytes were never higher than 6,500; the polynuclears and lymphocytes were variable though in normal range proportions; eosinophiles were not present. A few weeks before the death of the patient, Dr. S. W. Lambert suggested the possibility of Ebstein's variety of Hodgkin's disease, but prominent clinicians were quite in doubt as to the true conditions up to the time of his death. In the two cases that Dr. Hollis had seen, this one and another, periods of pyrexia and apyrexia alternated; in neither case were the superficial lymphatic glands implicated, but moderate splenic enlargement with some involvement of the abdominal and thoracic glands was a feature in both cases. He found no case reported of the typical variety of Hodgkin's disease which ran the striking temperature course of these two cases, yet because splenic enlargement and glandular involvement was always present they must, until pathology or bacteriology could demonstrate the specific difference or microbic cause, continue to classify such cases as a peculiar variety of Hodgkin's disease. The gross pathological findings at autopsy were a spleen more than twice the normal size which showed on cross section numerous whitish nodes hardly any larger than an almond; a very few similar but smaller nodes were found in the liver; and there were a number of very definitely enlarged mesenteric and bronchial glands.

A Case of Leontiasis Ossia.—Dr. KARL M. VOGEL made his report demonstrating his case with lantern slides (see page 214).

Dissecting Aneurysm of the Aorta and Ruptured Thoracic Aneurysm.—Dr. J. G. HOPKINS made this pathological report. The autopsy was performed the day after death. The anterior portion of the left pleural cavity was found filled with blood clot which extended about the root of the lung and up over the apex, amounting to 600 c.c. in volume. From a line running down about the middle axilla, backward, the lung was firmly bound down to the chest wall with a mesh of fibrin two cm. or more thick, which was saturated with a turbid yellow fluid. In the left upper quadrant of the abdomen a large mass was felt retroperitoneally above the left kidney. As no definite boundaries to this mass could be made out the organs were removed *en masse*. On section this mass was found to lie behind the posterior portion of the diaphragm and to consist of a large false aneurysm lying between the diaphragm and the diaphragmatic pleura. This had ruptured upward into the pleural cavity. The aneurysm opened laterally from the aorta by a huge gap measuring five cm. vertically and one cm. anteroposteriorly. The remnants of the arterial wall could be traced out for a distance of three or four cm. into the wall of the sac. Beyond this it was bound down by dense connective tissue and for the most part was filled with firm thrombus. It extended laterally 11 cm. and measured 11 cm. vertically and 5 cm. antero-posteriorly. The aorta also presented two other aneurysms. In the ascending aorta occupying the region of the fourth sinus was a small fusiform dilatation measuring 5.5 cm. in diameter. Beyond this the aorta narrowed greatly and at the isthmus measured three cm. in diameter, as did the descending aorta. Eleven cm. below the origin of the left innominate there was a small opening in the left wall of the aorta through which a probe could be passed into the sac of a huge dissecting aneurysm. This measured two cm. in average diameter and extended about two cm. above the opening into the main vessel. A short distance below this it branched, one branch communicating by a small opening with the neck of the ruptured aneurysm above described, the other passing posteriorly to the neck of this aneurysm and ending blindly a little below the level of the celiac axis, making the total length of the sac thirteen cm. The lower portion of the blind sac was filled with a firm thrombus. The upper portion of the lumen was free, and the wall smooth and glistening with numerous atheromatous plaques. Microscopically it was lined with epithelium. The aorta showed most extreme endarteritis. The changes were much more marked than was usual in cases of aneurysm. The orifice of the celiac axis which lay a little below the main aneurysm was restricted to a diameter of 2.5 mm., while the superior mesenteric just below this was dilated to 7 mm. across. The right renal was very large, while the left renal was much contracted; the suprarenal on this side being unusually large. These vessels beyond their origin showed little evidence of disease. The heart was hypertrophied and the myocardium showed very slight evidence of fibrosis. The aortic ring was thick and calcareous, but not appreciably dilated. The descending thoracic aorta was rather less frequently the seat of aneurysms than were other portions of the vessel, and this precise situation between the pleura and the diaphragm seemed rather unusual and Dr. Hopkins had been unable to find any recorded cases.

Anatomical Study of a Thoracopagus Fetus.—Dr. J. R. PAULING presented this specimen, which was one of identical or homologous twins, *i. e.*, having developed in a single amniotic sac and having resulted probably from a single ovum. Double monsters might be classified into two classes: First, those showing decidedly unequal development, and, second, those showing practically equal development. The specimen under consideration belonged to this latter class and might be termed an equal monosymmetrical thoracopagus. The thoracopagus was not really exact because the union in this case included not only the thorax but the upper part of the abdomen as well, for it would be noticed from the photograph taken before dissection that the cord sprung from the under surface of the bond of union. This same picture showed a double thumb. The development of these twins was that of a four months fetus. In order to show the relations of the viscera, one side of the specimen was removed completely. In dissecting up the skin the recti muscles were exposed and found to extend from the lower ribs downward and outward to each pubis. By making translucent that portion of the chest wall removed, they found that, instead of the sternum of each side coming in contact face to face, each sternum had split; that was, the front and the back of the specimen formed a separate sternum. The thorax, therefore, was common; it contained a single pericardium inclosing one heart having five chambers. The apex of the heart, as they looked at the specimen, pointed directly forward. The long axis of the heart was in a horizontal plane. Two aortæ left the two left ventricles, the arch in each fetus taking the normal direction. Two inferior venæ cavæ pierced the diaphragm and entered a common right auricle. This was continuous with a common left auricle. Into this common chamber entered also a pulmonary vein from the right fetus. The pulmonary artery of the left fetus appeared to be represented only by a fibrous cord, which extended to the root of the aorta, there being no right ventricle for that fetus, so that its lungs received blood only from its aorta by way of the ductus arteriosus. The course taken by the blood seemed to be as follows: Entering the common right auricle by the inferior and superior venæ cavæ, it reached the common left auricles, and thence to the two left ventricles and the two aortæ to the arterial system, but also partly back to the lungs through the ductus arteriosus of each fetus. Some left the common right auricle to enter the single right ventricle, then through the pulmonary artery of the right fetus to the lungs on that side. The lungs showed the usual divisions into lobes. The left lung of the right

fetus presented a cardiac incisure, which received the apex of the heart. The left lung of the left fetus was abnormal, in that a lobe hooked over the aorta and there was a groove accommodating the left superior vena cava which ran down between the outer surface of the left lung and the chest wall. The diaphragm was single and arched over a single liver. The upper part of the liver had a shallow groove in the median line from which a thin fibrous partition extended to the abdominal wall. The umbilical vein was single and entered the liver through a deep notch situated at about the center of this front surface. Above and below this the liver was continuous across. At each side of this there was a deep cut as if to represent what would have been an umbilical fissure in each liver. The umbilical vein followed into the substance of the liver, but the right branch also connected by a distinct vessel with the right inferior vena cava, this connection being a ductus venosus. The intestinal tract was very interesting. As the abdominal wall was opened a small pointed pouch about 0.5 cm. long was seen adherent to the inner surface of the cord. It was the remnant of the vitelline duct, or a Meckel's diverticulum. It opened into a horizontal loop of gut and was located at a Y-shaped junction formed by what they might call a common jejunum meeting the two ilea. Below this point each fetus had its own intestinal tract. Following upward this common jejunum they found that it continued single almost up to the stomach, where it joined a horizontal loop of gut made up of the two short duodena. The viability of such a monster seemed very unlikely even if it could have been delivered at term. Dr. Pawling discussed the underlying causes of the production of such monsters and stated that the evidence seemed to point to an external causation and to no inherent condition in the ovum or sperm. He had collected thirty-three cases of pathological ova and found that they could be classified into three groups: 1. In the first group of eleven cases a severe hemorrhage for several days preceded abortion; 2. This group of twelve specimens were abortions from newly married women or relatively sterile women; 3. This group of ten specimens were from women who had given birth to a number of healthy children and then began to abort, often two or three times. The specimen presented belonged to the third group.

A New Method of Diagnosis of Acute Intestinal Obstruction by the Stomach Tube.—Dr. HARRY G. WATSON presented this paper. He said that it was a sad commentary on the practice of medicine when it was learned that the mortality in cases of acute intestinal obstruction was nearly 50 per cent., and that this was mainly due to procrastination. In every case of acute intestinal obstruction "He who hesitates is lost." The diagnosis of acute intestinal obstruction was difficult. Among other conditions which were similar the most important was acute peritonitis. In acute peritonitis they usually had high fever, 102° to 104° F., marked distention, and rigidity of the abdomen, vomiting appearing early but more frequently in strangulation. The attitude of the patient was quiet in peritonitis, very restless in acute obstruction; in acute obstruction the temperature was normal or subnormal. The vomit soon became fecal and there was complete constipation. In peritonitis there was some movement. As a rule in acute obstruction peristalsis could be seen, and there was usually some gurgling. Some other confusing conditions which might be taken for acute intestinal obstruction were hepatic colic with gallstone history, nephritic colic, twisting of a pedicle of an ovarian cyst, and volvulus of the sigmoid. A careful history, pelvic examination, or finding blood in the urine would help clear up the diagnosis in these cases. Vomiting was one of the constant and most important signs in intestinal obstruction and the study of the vomit in every case of acute abdominal disorder was vital. They first got the ordinary stomach contents, later becoming greenish, mixed with bile, and later still a dark brown fluid with a fecal odor. This was a most important sign. If the obstruction was high up in the duodenum fecal vomiting might not be so marked. If the obstruction was in the ileum, fecal vomiting was present earlier, and the distention was more marked. The vomitus was frequently disposed of before the physician arrived and the patient could not vomit just when desired, hence as an aid to diagnosis in these acute abdominal disorders the stomach tube should be passed from hour to hour and the contents carefully noted. If they were of a dark brown color with fecal odor, ruling out peritonitis and other acute conditions mentioned before, then a definite diagnosis of acute intestinal obstruction could be made and immediate operation should be advised.

Brill's Symptom-Complex, Typhus, and Manchurian Typhus.—Dr. G. A. FRIEDMAN read this paper. He said that Dr. Brill had described a disease, infectious, of unknown origin and unknown pathology, characterized by an incubation period of four or five days, a period of continuous fever, accompanied by intense headache, apathy, and prostration, a profuse and extensive erythematous maculopapular eruption, all of about two weeks' duration, whereupon the fever abruptly ceased either by crisis within a few hours or by rapid lysis within three days, when all symptoms disappeared. Brill was right in stating that this disease was often taken by New York physicians for typhoid and this interpretation was incorrect. Neither did the disease in question have anything in common with the group of paratyphoid diseases, as was confirmed by the agglutination reaction in both instances. Brill in differentiating his symptom-complex from typhus fever said: "If it had been proved that typhus fever had lost its virulence, that it was constantly present in a community, that it was not communicable, that when it was present epidemics of it did not occur, and that it was no longer a grave and fatal disease, then the resemblance of the symptom-complex to this malady might be admitted." But Brill thought that with the description of typhus as the "great masters" had taught it and as he had seen it such a conception would be unjustifiable. Brill had failed to acquaint his readers with the view of modern or recent authors who had observed cases of typhus fever while possessing all the advantages of medical progress in differentiating other diseases from them, advantages which were absent in the times of "the great masters of medicine." The writer was in active practice in western Russia for six years, during which time he had the chance to observe three epidemics of typhus fever and constantly saw sporadic cases of the disease. The more the writer read Brill's descriptions, the oftener he listened to discussions of the theme, the more inclined he became to identify Brill's disease with typhus fever. The fairly sudden onset of the affection, the fever curve, the duration of the illness, its termination, the nature of the eruption, the time of its occurrence, the intense headache, the relatively frequent occurrence of herpes labialis, the rapid convalescence, the occurrence of the disease in patients who had previously had typhoid fever, the frequent enlargement of the spleen, the complications involving the respiratory tract, all these the writer had seen in authentic cases of typhus fever occurring during epidemics and independently of them. Brill emphasized the intense headache which dominated the clinical picture; other observers dealing with typhus fever had laid stress on this point. To the writer this was one of the most striking features of typhus fever as he had observed it. In regard to the skin eruption the writer had seen cases of the maculopapular type, but likewise other cases showing a roseola and petechiæ, or petechiæ alone, or roseola

alone. Intestinal complications such as frequently occurred in typhoid fever had not come under the author's observation. Brill had stated that typhus fever did not occur in the summer, but this statement was only partially correct; whenever there was an epidemic in the winter sporadic cases occurred the following summer. The writer had seen a repetition of typhus in the same individual. Typhus was endemic in many districts of Russia, so that sporadic cases were of constant occurrence there. In many other districts where hygienic conditions were very favorable typhus fever was but little known, and if sporadic cases did occur they were of mild character. When sporadic cases running a mild course occurred in large cities they were usually not recognized, or were designated as "uncertain kinds of typhus." Typhus was also endemic in other countries. Virchow assumed that the endemic typhus of the Slav led to the epidemic outbreak in Berlin in 1867-68. In Edinburgh typhus was practically endemic at one time. In Ireland, Italy, and Bohemia the affection was likewise said to be endemic. De Arellane stated that typhus fever was not endemic in the capital of Mexico, but was always present in a very extensive zone in the Republic. An epidemic in Edinburgh in 1899 proved that after eighteen years of immunity an epidemic might occur. From numerous similar instances they might conclude that in a community typhus might be present for a long time without leading to an epidemic. Dr. Friedman reviewed the history of the epidemics of typhus in New York City and stated that the mortality of typhus epidemics had considerably decreased through improved hygienic conditions and modern sanitation. The mortality of typhus fever in hospitals and private houses was not appalling, ranging from 6 to 9 per cent. In his sporadic cases there was rarely a death. Dillingham gave a description of "so-called typical cases" of typhus and if they were carefully analyzed and compared with Brill's cases the identity would be apparent. The fact that mostly Hebrews were affected among Brill's cases must be remembered; this race was usually but mildly affected by typhus. The same had been shown to be true of the Arabs. Time alone would decide the question of properly classifying the symptom complex so ably observed and described by Brill. In the meantime it did not seem to the author to be the part of wisdom to retain his nomenclature of a "disease of unknown origin," but rather call it New York typhus, just as the typhus of Pekin and of Manchuria had been named. This would go far in calling the attention of physicians to the clinical picture concerned and, moreover, not connote something surely rare and unusual. The name typhus need cause no panic for it was no longer equivalent to the terrifying news "*Hannibal ante Portas.*" Modern conditions had robbed this scourge of much of its terror.

Dr. Nathan E. Brill and Dr. E. Libman discussed this paper. The discussion was closed by the essayist.

THE ALUMNI ASSOCIATION OF THE ST. JOHN'S GUILD HOSPITALS FOR SICK CHILDREN.

Stated Meeting Held April 15, 1911.

Dr. Medwin Leale, President, in the Chair.

Arthrodesis in Infantile Paralysis.—Dr. Benjamin P. Farrell of New York, read this paper. He said that his object was to describe the operation as performed at the New York Orthopedic Hospital. In 1905 following the publication of Albert's article they attempted to stiffen the ankle-joint by denuding the articular surfaces of the astragalus, tibia, and fibula of their cartilages through an anterior incision. These cases failed to give bony union, as the denuded surfaces could not be brought into close contact. Whitman's method of astragalectomy was more satisfactory. Later seven cases were operated upon with fair success. In 1908 Jones first published in the *American Journal of Orthopedic Surgery* his operation for stiffening the ankle-joint. Since that time his method has been used in a large number of cases with success. In varus and valgus perfect results have been obtained through arthrodesis between the astragulus and scaphoid, internal and cuneiform os calcis and cuboid. It has been found that the age limit for the operations should be ten or eleven instead of eight years, as Jones advised. Since 1909 Hibbs' operation for stiffening the knee-joint as described in the *Annals of Surgery*, March, 1911, had been successfully employed. The class of cases in which this operation was indicated were those which had lost control of the knee by complete paralysis of the quadriceps. They otherwise would be doomed to a life of cumbersome braces with their attending discomfort and expense.

The O'Dwyer Forcible Respiration Apparatus for Children.—Dr. Joseph O'Dwyer presented this paper. (See page 576.)

Dr. Edwin Leale said that in asphyxia neonatorum so long as the heart continued to beat there was hope for resuscitation. The best way to accomplish artificial respiration was to pass a catheter directly into the larynx, and by this means to inflate the lungs. The old mouth-to-mouth inflation was defective in that it succeeded more in inflating the esophagus and stomach than the lungs. Dr. O'Dwyer's apparatus was simple and effective. The nozzle of the instrument for the ingress and egress of air firmly tamponed the upper aperture of the larynx and closure of the nostrils was not required. This instrument was particularly useful in those forms of asphyxia in which the reflexes had been abolished and in which other simpler means had failed. If they had not been abolished a dash of cold water, immersion in hot water, passing the finger into the anus, or one of the old forms of artificial respiration, preferably that of Schultz, might be successful. In a vigorous infant where there were a blue skin and a bounding pulse, evidences of venous engorgment, the asphyxia might be relieved by allowing a few tablespoonfuls of blood to flow from the cord. If shock were present nothing was of more service than immersion of the body in water at 100 to 105° F. As a last resort, when the heart has ceased to beat, direct compression of the heart against the thorax by the fingers of the left hand through the flaccid abdominal wall might be given a trial.

Dr. W. M. Hartshorn spoke of the use of the O'Dwyer apparatus in cases of asphyxia following overdoses of morphine. He referred to a case requiring artificial respiration for twelve hours, in which such an apparatus would have been of value.

Laparotomy in Irreducible Retroversion of the Gravid Uterus.—Goullioud states that in case of the early discovery of retroversion of the uterus in pregnancy the reduction may be easily accomplished by the use of a Hodge pessary, which will maintain the uterus in its natural position. Later this becomes impossible, and the author introduces two fingers of the right hand into the vagina and reaches upward toward the promontory, crowding before him the fundus. When it rises it is pushed forward and the fundus assisted by the left hand in falling forward. In some cases assistance may be given by the inflated rubber baloon of Gariel. When incarceration has occurred and cystitis with retention of urine is present, constipation absolute, with pain in the pelvis and edema of the vagina and vulva, some operative interference is the only course that will prevent death from gangrene of the neck of the bladder compressed against the pubic bones. In some cases laparotomy and fixation of the uterus to the abdomen may be done without interruption of the pregnancy taking place. The chief obstacles to reduction are adhesions—the result of perimetritis or parametritis— and bands of congenital origin.—*Annales de Gynécologie et D'Obstetriques.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

ON THE VALUE OF RADIUM TREATMENT IN CANCER OF THE DIGESTIVE TRACT.*

By MAX EINHORN, M.D.,

NEW YORK,

PROFESSOR OF INTERNAL MEDICINE AT THE NEW YORK POSTGRADUATE MEDICAL SCHOOL.

As yet no specific against cancer has been discovered. Localized foci of this affection can, if recognized sufficiently early, be removed surgically and can at times be successfully cured. The clinician must, therefore, strive to make the diagnosis of malignancy early. This, however, is not always possible in the digestive tract. Frequently enough we are confronted with conditions that render operation impracticable. For these cases the radium treatment appears to me to have a great future.

Seven years ago I [1] had already written upon this subject. In cancer of the esophagus I[2] have frequently obtained good palliative results: the strictures became less narrow and the patient could take food and lead an endurable existence. This I have often seen.

In the present paper I would like, first, to say a few words about the instruments used for the radium application in the digestive tract, and then discuss the value of this method in the treatment of cancer of the stomach, pylorus, and rectum.

Technique.—Since radium must be applied for some length of time, it is important to construct the instrument in such a manner that it should not annoy the patient. As an improvement on my former efforts I consider the radium holder with whalebone stem (see Fig. 1).

Its handling is simple and its application not disagreeable to the patient. The instrument is suitable for the treatment of cancer of the esophagus and stomach. Whereas, however, in the esophagus the radium can easily be applied at the desired spot, thus exerting a powerful action upon the part affected, this cannot be accomplished in cancer of the stomach. Here the radium cannot be applied always in the most effective manner. If the cancer is at the pylorus, it causes grave early symptoms through narrowing of the canal and limitation of the food supply. If, as in the esophagus, we could apply the radium exactly to the affected spot, the therapeutic result would be considerable. It could then be hoped that in favorable cases the strictured pylorus might become more permeable.

I have, therefore, constructed for this purpose an instrument for the application of radium to the pylorus. It consists of a radium receptacle with a long whalebone stem; the capsule for the reception of the radium is provided with a small canal on its side, through which a thread can easily be passed (see Fig. 2). The method of radium application to the pylorus is accomplished in the same manner, as I [3] have described for the catheterization of the pylorus. The patient swallows, the night previous, either a small duodenal bucket or a metal olive, attached to a long braided silk thread; the length of the thread is such that 75 to 80 cm. can enter the digestive tract and the end is attached to the shirt. On the following morning, in the fasting condition of the patient, we see whether the bucket or the olive lies beyond the pylorus or in it. If this is the case a slight resistance is felt when we pull at the thread. In the stomach there is usually no such resistance felt. The thread is now cut near its attachment and drawn through the canal of the capsule and the latter is pushed along the thread by means of the whalebone stem, first into the mouth, pharynx, esophagus, and finally the stomach of the patient, slowly and without exertion of force, until an unsurmountable resistance is encountered. The latter is the strictured place. The capsule of the instrument now lies exactly at the spot we wish to treat with the radium. We, therefore, leave the instrument lie there for one-half to one hour, after again attaching the thread to the nightgown of the patient. When the time for the application of the radium has elapsed, the radium holder, the olive, and the thread are slowly withdrawn.

Occasionally it is desirable to leave the radium for a longer period (6 hours or more) in the digestive tract. It is then necessary to have the radium capsule exactly at the diseased focus. The hard rubber capsule devised by me and attached to a thread would be serviceable, but in swallowing the capsule we cannot tell whether we have touched the affected spot. The whalebone instruments are also unsuitable, because they exert too much irritation in the throat of the patient, if left in for any length of time. I have, therefore, constructed a "radium introducer" (Fig. 3). It consists of a spiral metal sound, covered with rubber, and a mandril. For a longer application of radium we use a capsule hollowed out in its upper end. The introducer is inserted into the hollow part of the capsule, the thread is drawn tight and pressed against the rubber tube. In this position the capsule is pushed to where it is wanted (esophagus or stomach). Now the mandril is first removed. This causes the capsule to lie free. Then the rubber tube of the introducer is slowly and carefully removed. We now have the capsule with the radium at the seat of the disease, and the thread emerging from the mouth of the patient is attached to the clothing. This procedure is not connected with any disagreeable symptoms for the patient and the capsule can be retained in the digestive tract as long as desirable.

My Latest Experiences in the Radium Treatment of Cancer of the Digestive Tract.—Since I wrote

*Read before the German Medical Society of New York on June 5, 1911.

a few years ago on the value of radium treatment in cancer of the esophagus I have made numerous new observations, which form only a confirmation of my previous communications. I would like to describe only two new cancer cases of the esophagus, in which the new instruments here described were used. Furthermore I made the trial in both patients of leaving the radium (70 mg. of strongest pure radium bromide) for a period of six hours at the affected spot. This prolonged and strong radium application I have tried in both these cases for the first time.

Case I.—Feb. 28, 1911. Carcinoma cardiæ. Max S., about 67 years old, suffering since October, 1910, from dysphagia. At first the patient noticed that he could not swallow solid food without drinking a great deal of water at the same time, in order to force it down. He had also had cramp-like pains in the esophagus, and occasionally vomited. Soon he also experienced difficulty in swallowing water, being able to take only a little at a time. After having partaken of food he would be compelled to lie down, in order to retain it. He never had hematemesis or melena. Since the beginning of his trouble the patient had lost over 25 pounds and had become much weaker. Examination shows that the swallowing sound is absent; bougie (39 F.) meets with resistance at 43 cm. from the teeth.

March 17. Patient was admitted to the German Hospital. Examination with the sound on this day showed: Bougie (43 F.) meets with resistance at 42 cm. from the teeth. The diagnosis of carcinoma cardiæ was made. Although the patient could not swallow even liquids comfortably, he did not wish to have a gastric fistula established. We decided, therefore, to treat him with radium. The affected spot was thus treated daily for one-half hour with radium. A few days later the patient could take his food much more easily.

March 25, 1911. Bougie (43 F.) met with resistance of 44 cm. *i.e.* the sound entered 2 cm. deeper than before the commencement of the treatment.

March 27, 1911. A swallowing sound was audible 17 seconds after the injection of water at the ensiform process. The patient could now take semisolid substances. The pains were also much less. Since the patient came from out of town and did not desire to remain long in the hospital, I decided to prolong the radium application in order, if possible, to obtain a more lasting effect. On March 28, therefore, I introduced the radium capsule (containing 70 mg. pure radium bromide) by means of the introducer, and left it for six hours at the seat of the disease. The patient felt no ill effects and stood the application very well. A week later the swallowing sound was audible after 12 seconds. At all events the patient had been materially improved by means of the radium treatment.

Case II.—February 15, 1911. Carcinoma cardiæ et ventriculi. Samuel K., about 40 years old, began to suffer about 3 years ago from gastralgia and vomiting. In 1909 the patient was operated upon for a tumor of the stomach. Since then he has been running down more and more. For about 3 months he has suffered, besides his anorexia, from difficulty in swallowing. Examination made on February 15 revealed a resistance of the size of a walnut under the left border of the ribs. The swallowing sound was absent, and a sound (39 F.) met with resistance at 42 cm. Shortly after admission to the hospital he had a severe internal hemorrhage (melena), from which he nearly died. After a few days, however, he rallied sufficiently to undergo an instrumental examination.

The patient received an application of 70 mg. of pure radium bromide for one hour on March 7, 9, and 15. On March 22 and April 1 he had applications of six hours' duration. His condition visibly improved during the treatment. The resistance at the epigastrium was no longer palpable and the patient could take mushy and soft food without difficulty. On March 27, 1911, the swallowing sound was present after six seconds. Examination with the bougie (43 F.) shows on March 30, 1911, resistance at 43 cm. bougie (25 F.) meets with resistance at 44 cm. The patient has gained considerably in weight and in strength.

Case III.—March 5, 1911. Carcinoma ventriculi. Louis S., about 58 years old, has been suffering for 7 or 8 years from grave disturbances of digestion. About 4 years ago, and then later 3 years ago, the patient had severe gastric hemorrhages. In the meantime there was intense hyperchlorhydria. The diagnosis had then been made of gastric ulcer and with bismuth, rest, and dietary treatment the patient got well and felt well for about 2 years. Then he had again severe hematemesis, accompanied by a resistance in the region of the stomach. The stomach contents showed absence of free HCl, presence of lactic acid and of occult blood, and slight ischochymia. It was fair to assume from these new findings that a malignant neoplasm had developed on the basis of the old ulcer. An operation was therefore advised and performed at a Brooklyn Hospital. A tumor was found at the stomach that could not be resected. A gastroenterostomy was therefore established. The patient then felt well for about six months, when he again began to suffer from digestive disturbances. For the last ten weeks he complains of pain in the epigastrium and frequent vomiting. The vomited matter consists of foul smelling substances, and he says frequently contains blood. The patient has since lost a great deal in weight, feels weak and sick, sleeps poorly, and suffers frequently from singultus and obstinate constipation. Examination revealed a tumor the size of a fist in the upper abdomen, lying nearly in the middle, a little above the umbilicus. Its surface was uneven, and it was of hard consistence.

March 6, 1911, washing of the stomach in the fasting condition shows the presence of decomposed food. In the stomach contents we can readily see unchanged blood. Chemically HCl is absent, lactic acid and blood are present. Microscopically large numbers of Oppler-Boas bacilli are visible. After washing out the stomach radium was introduced into this organ and left there for several hours. To state more correctly 70 mg. of pure radium bromide

Fig. 1.—Radium Receptacle for Stomach and Esophagus with Whalebone Stem.

was left in the stomach for five hours and twenty minutes on March 21, for five hours and fifteen minutes on March 23, and for full six hours on March 27, 1911. During the treatment the vomiting ceased, the pains were less, but the tumor failed to decrease in circumference. Fourteen days after the last radium application there was no decrease in the size of the tumor.

Case IV.—October 13, 1910. Carcinoma pylori. Robert D., about 65 years old, has been suffering for 4 or 5 months from increasing digestive disturbances. At first he had severe heartburn after meals and then pains and vomiting. The patient had lost about 40 pounds and complained of severe burning in the pit of the stomach, belching, pains, and vomiting of large quantities of acid matter. Examination revealed a markedly dilated stomach with visible peristaltic restlessness. Examination with the tube in the fasting condition showed the presence of food from the previous day; HCl present, also occult blood and sarcinæ.

The duodenal bucket (23 F.) was introduced on the evening of October 14, before the patient retired, and removed the next day. In withdrawing the thread slight resistance was at first felt. The bucket returned with foul-smelling, blood-tinged contents. The thread near the bucket and above it for some distance was discolored brownish. There was no bile on the thread. The thread test plainly showed that the bucket could not pass the pylorus, but was kept in a niche and filled up with bloody necrotic contents. The thread test combined with the examination of the stomach contents and the history pointed to a malignant trouble at the pylorus.

After a consultation with Drs. King and Pollock it was decided, in view of the advanced age of the patient, not to operate. Since the neoplasm involved the pylorus, it seemed advisable to apply the radium directly to this outlet. I then constructed the instrument above described. The patient was now treated twice weekly with hourly applications of 70 mg. pure radium bromide to the pylorus. The stomach was besides washed out in the fasting condition. The patient was placed upon a liquid diet and received chloral hydrate, 6 grams; distilled water, 200 grams; a tablespoon t.i.d., before meals.

Result of Thread Test in Robert D.

Date	Bucket or Olive No.	Impregnation of Blood	Bile Stains at
Oct. 15, '10. . .	B.	43–56 cm.

Nov. 12, '10 . . .	Olive 15 F.	0	
Nov. 15, '10. . . .	Olive 13 F.	0	
Nov. 19, '10 . . .	B	0	Yellow 64–68 cm

A short time after the beginning of the radium treatment the patient began to feel better. He had no pains, the heartburn disappeared, and he slept well. The improvement could also be noticed objectively. Since the radium was always introduced over the thread of the duodenal olive, an examination could always be made for the presence or absence of blood impregnation on the thread. It was shown that while the threads of October 15, 19, and 22, 1910, revealed marked blood impregnation between 37 and 50, or beyond, subsequent threads at first showed only a little and later no blood at all. We will tabulate the results of the thread test as follows:

On November 5 the olive (13 F.) passed deep into the duodenum and showed a golden yellow discoloration between 65 and 80 cm. Olive No. 13, however, never again passed through.

The retention of food at first was of a high degree, becoming a little less, and remained that way for some time, only to become more intense later on. Thus we obtained from the fasting stomach in the morning on October 20, 500 c.c.; October 24, 400 c.c.; on October 27, 395 c.c.; on October 28, 350 c.c.; on November 3, only 300 c.c.; then the retention became steadily greater, being, on November 4, 700 c.c.

The weight of the patient showed at first a slight increase and then dropped steadily. He weighed on November 4, 155½ pounds; on November 7, 157 pounds; November 12, 158 pounds. On November 22 the patient left the hospital and a similar course of treatment was followed at his home. In October a resistance developed at the smaller curvature of the stomach in the epigastrium. It grew steadily

Fig. 2.—Radium Receptacle for Pylorus, with Whalebone Stem.

and the peristaltic restlessness of the stomach became more marked. The subjective health of the patient remained rather good. In spite of the constant loss of weight through the impermeability of the pylorus, the patient could take a daily walk and was in fine spirits. Finally he began to have fainting spells and 2 or 3 days later he died in collapse.

Case V.—January 16, 1911. Carcinoma ventriculi. Daniel S. B., 67 years old, was always in good health until 6 months ago, when he began to suffer from digestive disturbances. The appetite was poor and pains occurred soon after meals. Soon vomiting set in, and the patient lost steadily in weight and became weaker and weaker. When he consulted me he looked pale and emaciated; he could hardly walk without support and stated that he had lost about 40 pounds in weight. Physical examination revealed a distinct resistance in the epigastrium, which seemed to be localized in the lesser curvature of the stomach. The stomach was dilated and reached 2 or 3 fingers below the navel. The liver was enlarged, prolapsed, and seemed to be harder than normal. This caused suspicion of a secondary neoplasm in this organ. Examination with the tube showed the presence of food remnants from the day previous, absence of HCl, presence of lactic acid, and numerous Oppler-Boas bacilli.

We had here to deal with an advanced case of cancer of the stomach, involving the lesser curvature and probably the pylorus. In view of the great weakness and advanced age of the patient, Dr. Shelton and myself decided to defer operative in-

terference and to treat the patient expectantly. The patient was accordingly placed on a liquid diet and the stomach was washed out every other day. In this way the stomach showed no retention of food, but in the washwater mucus with a great deal of black blood was at first always found.

The duodenal bucket was introduced on January 16, and removed on the next day in the fasting condition. There was no resistance encountered; the length of the thread was 68 cm. Between 50 and 68 cm. the thread was discolored from blood; the bucket contained foul-smelling, decomposed blood.

January 20. Lavage; blood visible microscopically.

January 21. Radium treatment was begun. Twice weekly 0.07 gm. pure radium bromide was introduced into the stomach for a half hour by means of the whalebone instrument. One day after the first application (January 22) lavage of the stomach showed no blood, and this remained thus for a long time with one exception (February 13), when a quantity of blood was again observed on lavage.

January 27 the thread test was performed with olive (15 F.), showing thread length 73 cm.; greenish discoloration between 55 and 73 cm.; at 68 to 70 cm. were several suspicious brown spots. This test also showed a diminution of the bleeding spots in the stomach. The patient felt much better; he had hardly any pain, became stronger and looked better (he was not as pale as formerly) and gained in weight. Toward the middle of February he had gained 8 pounds in weight. At the end of February, 1911, another consultation between Drs. Shelton, Lloyd, and myself was held and, in view of the improved condition of the patient, an operation was deemed advisable. The patient was then operated upon in Rochestser, Minn., by Dr. W. H. Mayo, a gastroenterostomy being made.

Case VI.—December 20, 1910. Carcinoma pylori. Louis L., 75 years old, has been suffering for 5 months from pain in the epigastrium and frequent vomiting. He lost constantly in weight and in strength. Dr. N. Sobel sent the patient to me with the diagnosis of carcinoma of the stomach. Examination revealed the stomach much dilated, extending a hand's width under the navel and showing peristaltic restlessness. A resistance could not be discovered on palpation. The stomach tube brought up foul-smelling, coffee-ground material, with food remnants from the previous day; HCl was absent, lactic acid, also Oppler-Boas bacilli, was present. The examination with the duodenal bucket on December 20, 1910, showed: Thread length 60 cm.; no resistance in withdrawing it; thread brownish at 50 to 60 cm. The bucket, therefore, did not pass the pylorus and showed a light brownish discoloration in its vicinity.

The diagnosis of Dr. Sobel was therefore correct in every way. An operation in this case could not even be thought of and the patient was accordingly sent to a nearby health resort at his own request. He was placed upon a fluid diet and his stomach was washed daily. He ran down quickly, and returned to New York on January 22, 1911. He was admitted to the German Hospital, being so weak that he could scarcely sit up. Every change of position was accompanied by fainting spells.

The physical examination showed no change. A duodenal bucket test (17 F.), on January 24, showed a marked bloody discoloration from 57 to 60 cm. Lavage showed ischochymia of a high degree and dark brown, bloody masses. For 3 weeks the patient was treated with half-hourly applications of radium twice weekly as in Case V. Although the ischochymia remained, the brown coloration of the chymus soon disappeared. The patient had less pain and felt somewhat stronger. The ischochymia, however, did not decrease and the patient kept on losing in consequence of the inanition until he died.

Case VII.—January, 1909. Carcinoma recti. Mrs. B. B., about 70 years old, had suffered for 6 or 8 months from severe abdominal pains, frequent desire to go to stool, and mucosanguineous diarrhea. She had lost considerably in weight and looked pale and slightly cachectic.

On examination per rectum the finger encounters high up an irregular tumor, not connected with the uterus; on withdrawal the finger showed mucus with decomposed blood. An operation was refused by the family physician and the patient. Radium treatment (application of radium, 0.25 gm., Curie 20,000 strength, per rectum to the tumor) was begun, and used for nearly two years every day for one hour. The hemorrhages ceased after a few weeks and the pains grew less. Then patient was left for about four months without radium treatment. When, however, the pains returned one application of 0.07 gm. pure radium bromide was made for 6 hours at one time. During this application the patient was lying with her pelvis elevated in order to effect a better contact of the radium with the tumor. She stood this very well and the application seemed to exert a good influence. It is now three years since the trouble began and the patient still leads a comfortable existence. She receives company, eats at the table with her family, and seems to have little trouble. The tumor is still plainly palpable, but does not bleed.

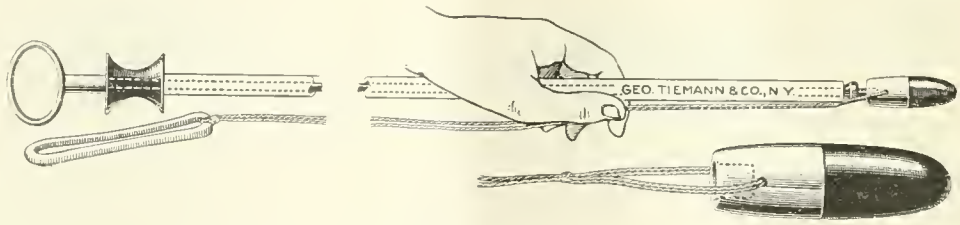

Fig. 3.—Radium Introducer.

Epicrisis.—If we analyze the cases treated with radium and described above, we find that this mode of treatment alleviated considerably the dysphagia in two cases of advanced cancer of the cardia and caused the swallowing sound, which at first was absent, to return. In one of them a small tumor, the size of a walnut, which before treatment was plainly perceptible, could not be demonstrated later. Whether this disappearance of the small tumor came about by the shrinkage of the tissue or whether it was only apparent, being caused by a change of position, I am unable to say.

Applications of 0.07 gm. of pure radium bromide for periods of 6 hours caused no disturbances and were followed by good results.

We now will consider the following four cases of cancer of the stomach and pylorus. In one case (L. S.) a gastroenterostomy without the removal of the tumor had been performed six months previously. The old symptom (steady vomiting), however, had returned. There was grave ischochymia and blood was easily recognized in the stomach contents. After the use of radium the vomiting ceased, retention was less, and blood was no longer present. The tumor, however, did not decrease in size. In the other 3 cases there was a marked diminution of the bleeding into the stomach. In two (R. D. and D. S. B.) there was first a marked improvement with some gain in weight. In R. D., where the applications took place directly to the pylorus, the latter became for a short time more permeable. A decrease of the pains was apparently present in all of these cases.

In case VII we have an advanced case of cancer of the rectum, in which the application of the radium caused a cessation of the bleeding and pain, and undoubtedly prolonged life.

If we consider that in all these cases we have to deal with separate conditions, where until now our only treatment has consisted in increasing doses of opium or morphine, we may be contented with the results of the radium treatment.

It would, of course, be more satisfactory if I could report a cure. This has, however, not been the case, although the possibility is not excluded. Long-continued applications of strong radium may, if inaugurated sufficiently early, be crowned occasionally with entire success. I am, however, ready, on the basis of my experience, to recommend highly the direct application of radium in inoperable cancer of the digestive tract.

TWO CASES OF LITTLE'S DISEASE.

BY M. NEUSTAEDTER, M.D., PH.D.,

NEW YORK.

ATTENDING NEUROLOGIST NEW YORK UNIVERSITY AND BELLEVUE COLLEGE CLINIC, BELLEVUE HOSPITAL O. P. D., ST. MARK'S HOSPITAL O. P. D.

LITTLE'S disease, or congenital or acquired spastic paraparesis, is characterized by a generalized rigidity of the muscles of the trunk and extremities, and in some cases even of those of the neck and face, but usually confined to the lower extremities. True paralysis is not a marked feature. Intelligence as a rule is not impaired. Strabismus, nystagmus, and convulsions may be present.

Struempell first described this variety of paraplegia, and later Bernhardt, Tooth, Erb, Hochhaus, Nenmark, Raymond, Kuehn and others have reported cases of this character. One cannot get a definite picture, however, from the reported cases so far as the degree of the affection is concerned, as is the case in other nervous affections of an hereditary type. While cases in one family show a decided similarity of type, other reported cases betray other forms of spastic paraplegias. In a case reported by Sachs, a poliomyelitis seems to have been superimposed on Little's disease.

It is seldom that several generations are afflicted with this disease; as a rule it occurs in one family, in which the hereditary taint manifests itself in the presence of other neuroses of the progenitors. The males are more often attacked than females.

Little has shown that the most important cause is immature birth, but a protracted and difficult labor or a forceps delivery is a frequent etiological factor. Furthermore, inflammatory processes, or a defective development, or a cortical agenesis of the motor area during fetal life play an important part in the prenatal etiology. Friedman, De Amicis, Rolly, Déjerine and others have shown that hereditary syphilis is also an underlying cause.

FIG. 1.—Case I, under treatment.

The traumatic influences produce either meningeal hemorrhages in the motor zone or in a circumscribed area, such as the leg center, or a degeneration or inhibition of development of the pyramidal tracts without any cortical lesion, either of which lesions produces a congenital spasticity of the extremities. In other cases encephalic processes lead to an induration or atrophy of solitary convolutions or even to porencephalitis. A symmetrical lesion, of such a nature, in the motor areas of both hemispheres will necessarily cause a spastic paraplegia.

Gehuchten, Souques, Erb, and Déjerine include under this category cases of a purely spinal origin

as well. In these cases, it has been shown, the lesion begins in the cervical portion of the spinal cord with a consequent descending degeneration in the lateral tracts.

The symptomatology of this disease is so well

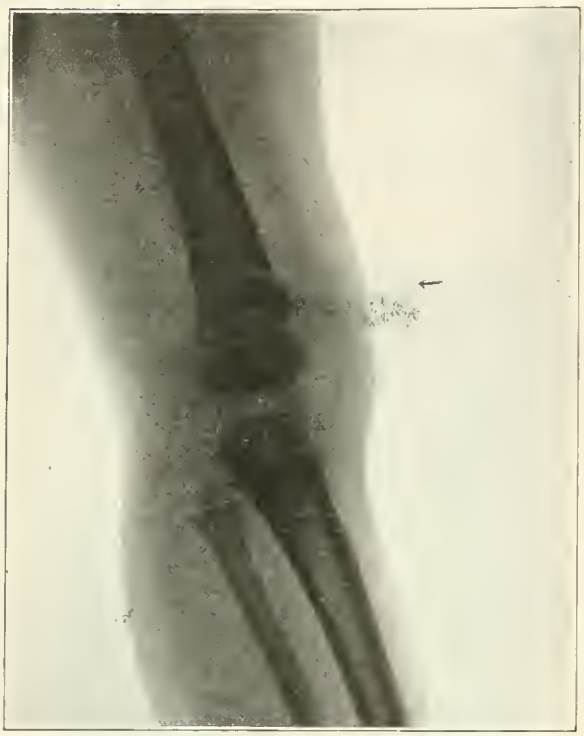

Fig. 2.—Case I, the arrow points to the patella.

marked in my cases, that I will proceed with the description of these.

Case I.—L. F., female, 3½ years old, born in United States of Galician parents of a rather neurotic temperament. The existence of syphilis, alcoholism, or rheumatism is denied. Patient was born after 7 months' gestation and after a hard labor lasting 11 days? (statement of mother). No instruments were used. She was a mixed breast and bottle-fed baby. When 5 months old she began teething without convulsions; at the age of 1 year she started to sit up and at 1½ years began to take steps; unaided she cannot walk as yet. At 14 months she began to talk. She was always quite intelligent. Five weeks ago she had measles, otherwise has had no disease. With the exception of enuresis nocturna, which subsided with the onset of measles, she was at all times of clean habits.

Physically, the upper part of her body is not affected, but the lower extremities present a marked spasticity on account of the rigidity of the muscles. The thighs are pressed together and when separated with some difficulty recede at once into the position of adduction as soon as force is removed. The gait is a pathological one, the legs are held stiffly in a semiflexed position, with the thighs rotated inwardly and markedly adducted, so that the knees nearly touch each other. This condition is so pronounced that during the act of walking the feet cross each other. The walk is maintained on the toes with the heels uplifted. (Figs. 1 and 3.) The legs are thrown forward as though they were of one piece, the pelvis being respectively raised or lowered. The rigidity of the muscles of the left extremity is more marked than of the right, while the motor power is fairly good in both. Patellar reflexes are markedly exaggerated, ankle clonus is present in the left extremity only, and the toe extension reflex (the Babinski sign) is present in both feet. The ligamentum patellæ is very much elongated, so that the patella is fairly pushed upon the femur beyond the condyles. (Fig. 2.) There are no sensory disturbances.

Case II.—M. F., male (brother of above patient), 2 1/3 years old. Born after 9 months' gestation and very easy labor. He was a breast-fed baby. When 7 months old he began teething without convulsions; when 1½ years old he began to sit up; he does not walk yet, but takes steps with difficulty, when aided. He was 14 months old when he began to talk. Has enuresis nocturna, but otherwise is of clean habits and quite intelligent. Had measles and scarlet fever a few weeks ago, but is quite well now.

Physically he presents the symptoms of his sister in a more marked degree. (Fig. 3.) The ligamentum patellæ is not as elongated as in case I (Fig. 4), because he is not as old, therefore the patella is not as high up as in Fig. 2.

It is characteristic that the epiphyses of the bones in both cases are very far apart and present

Fig. 3.—Case II, showing the spasticity.

a rather delayed ossification in all bones. In Case I there is a faint point of ossification in the patella. There are two explanations offered for the elongation of the ligamentum patellæ in these cases. It may be due to a constant stretching of the ligament

by the rigidity of the muscles and a consequent limited motion in the knee joint. Frasser, Roux, Marey, and Joachimsthal have shown in a number of experiments that as a result of a long limitation of movements in an extremity there results a short-

Fig. 4.—Case II, the arrow points to the patella.

ening of the muscle and an elongation of its ligament. In the case of Little's disease there is still another explanation, namely, that there is a delayed development of the muscular tissue on account of the constant rigidity and stretching and the consequent immobility of the joint. This phenomenon is characteristic of Little's disease, as we seldom meet with it in other spastic affections of the lower extremities occurring in later life.

CHORIOEPITHELIOMA MALIGNUM.

REPORT OF A CASE FOLLOWING ABORTION; OVARIES RETAINED; COMPLETE RECOVERY; WITH DETAILED REPORT OF THE PATHOLOGIST.

By WM. H. DUKEMAN, M.D.,

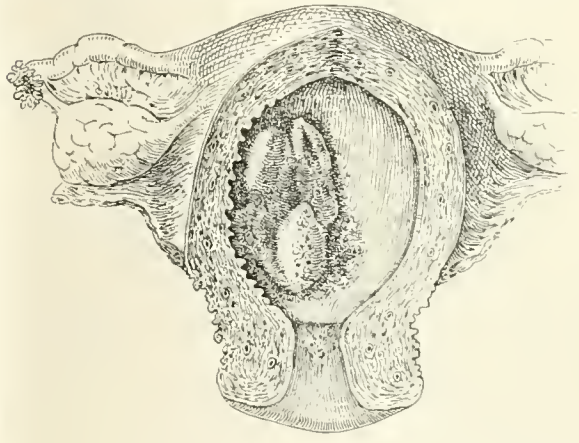
Los Angeles, California.

This malignant uterine tumor was originally described by Sänger of Leipzig in the year 1888. The two cases then described by Sänger were soft, spongy tumors which developed in the body of the uterus following abortion. Metastases developed in other tissues remote from the original site of the tumor and he then believed the growth to belong to the sarcomatous group. He termed the growth "deciduoma malignum." Since then pathologists the world over have studied the disease and its true histopathology is now clearly defined. Less than 300 cases have so far been reported.

Histology: The tumor is made up chiefly of large blood spaces with walls consisting of large, clear cells with vesicular nuclei and vacuolated protoplasmic masses containing several deeply stained nucleoli resembling syncytium. It is sometimes called syncytial cancer. The disease has its origin in the syncytial cells of the chorion villi. The syncytial-like masses are especially abundant about the margins of the tumor and have the tendency to penetrate the walls of the blood vessels and is thus carried into the general circulation, causing metastases. Only rarely are the lymphatic glands involved. Chorioepithelioma malignum has no stroma which distinguishes it from carcinoma. In sarcoma true syncytium or structure resembling the early villi of chorioepithelioma are not found.

Etiology: There is no known cause. But that the disease follows a pregnancy or an abortion is a known fact. Sometimes a hydatid mole precedes its appearance. It is not known whether the disease develops during pregnancy, or after labor, or abortion, or how long after it makes its initial appearance. The average time when the tumor presents its first symptoms is about five weeks after labor at term, seven weeks after abortion and after hydatid mole the time varies from several weeks to five years.

Symptoms: Hemorrhage is the first symptom and continues to be the most prominent symptom throughout the entire course of the disease. The hemorrhage at times is quite profuse and persistent and when it abates will reappear again without any known special cause. Later when the tissue of the



Showing Location of the Tumor.

tumor breaks down the discharges with the blood become foul. The body of the uterus becomes larger than normal and is soft and boggy. The os is patulous and dilated and the examining finger may be introduced into the uterine cavity and the lobulated like mass may be recognized.

Diagnosis: Unfortunately the disease cannot be accurately diagnosed from uterine curettings. It is only from sections of the uterine wall with decidua and villi, showing the characteristic blood sinuses, surrounded by the large, clear cells of Langhans and the invading syncytial masses that the nature of the disease is recognized. Chorioepithelioma malignum occurs most frequently between the ages of twenty and thirty and usually proves fatal in six or seventh months. It sometimes occurs later in life.

Treatment: In its earliest stages, could the disease be clearly defined, curettegé would appear to be the most rational treatment. Later in the disease nothing short of hysterectomy is advisable.

Report of Case: Mrs. F. E. D., age 29, weight 100 pounds, normal weight 135 pounds, married, mother of two children, both living, ages respectively 7 and 5 years. Nine years ago patient underwent a mastoid operation. At last childbirth, five years ago, she was confined to bed for several

weeks with puerperal fever, due to retained piece of membrane. She was not curetted, but her physician called in consultation Dr. M. L. Moore and Dr. W. W. Beckett, who advised cleansing the uterus by intrauterine irrigations. She recovered. During the year following her menstruations were irregular, going over time, and a little more profuse than normal. Three years ago she became pregnant and miscarried at about the fifth month. During the pregnancy she menstruated irregularly. She was confined to her bed again for several weeks. Losing confidence in her attending physician she discharged him and consulted a Chinese doctor, who administered the usual mysterious decoctions, and in time a mass of retained membranes were expelled. This siege of sickness again reduced her health and she only weighed about 95 pounds. She remained under the Chinaman's treatment for about one year. Her health gradually improved and she regained her normal weight and was in better health than before the miscarriage. During the past two years at intervals of several months she menstruated profusely and on three occasions passed growths from the size of an orange to that of an egg. She consulted Dr. J. T. Stewart about one of these growths, who pronounced it a submucous fibroid. Last December she passed the last growth, about the size of an egg. Her menstruation continued irregular, usually going over time. Her last menstruation was in the early part of February. Her menstruation not appearing by the latter part of March and thinking she was pregnant and not wishing any more children she attempted to produce an abortion by shoving a catheter containing a stilette into the uterus the best she could. The result was a profuse hemorrhage. She became alarmed and called in Dr. J. Colvin Brown, who found her almost exsanguinated. The writer was called in consultation and the uterus was irrigated with hot (temp. 120° F.) boric acid solution, which controlled the hemorrhage. The uterus felt hollow as after labor. By bimanual manipulation a growth was diagnosed on the right side of the uterus. The hemorrhage reappeared in a few days and Dr. Brown sent a scraping to Dr. E. L. Leonard, who reported epithelioma. The writer was again called in consultation. Examination by speculum showed a soft enlarged cervix; there was no visible excoriation or visible signs of carcinoma. The os was very patulous, admitting the index finger, and a mass in the uterine cavity, as previously outlined, was felt and its true nature suspected. Hysterectomy was advised and the patient was sent to the Clara Barton Hospital.

May 1 operation was performed by the writer, assisted by Dr. J. Colvin Brown and H. G. Marxmiller, Dr. F. D. Bullard, anesthetist. The abdomen was opened in the median line and the omentum, intestines, and line of incision were walled off with large, moist gauze pads. The uterus grasped in the hand was gently drawn up, it was soft and enlarged; the ovaries and tubes were apparently normal. There were no enlarged glands to be felt anywhere. A supravaginal amputation was done a little below the internal os. As the ovaries and tubes were, to all appearances, normal they were retained. No clamps were used. The arteries were doubly ligated and divided between ligatures, thus avoiding any loss of blood or bruising of tissue. All raw surfaces of the peritoneum and cervix were carefully coaptated and turned in by continuous suture. The abdomen was closed in layers. The wound healed nicely and on the tenth day the stitches were removed, and the patient left the hospital on the seventeenth day. She is up and around and apparently well. As metastases in these cases most frequently develop first in the lungs and the vagina, and later in other internal organs, and as the disease is transmitted through the circulation of the blood, and not by the lymphatic system, I decided not to disturb the apparently healthy ovaries, concluding that by retaining the ovaries the vitality of the patient would be better preserved and the ovarian secretion (for one of her age) would possibly act as an agent in assisting, at least, as a preventive aid against metastases. Whether there will be a recurrence of the disease by metastases, as is the usual course of this disease, time only will tell.

It is now four months since she underwent the operation and there is no evidence of any kind of a return of the disease. In fact, she is feeling remarkably well and has gained 30 pounds in weight.

A section of the uterus and growth was sent to Dr. C. C. Warden, pathologist, who reported chorioepithelioma malignum. Herewith is appended the pathologist's report in full:

The gross specimen consisted of a uterus, slit open to show the cavity, of about normal adult size. The external surface, the body, and a portion of mucosa appeared normal to the eye. Attached to one side of the interior and covering nearly all of one-half of the surface was a soft, friable, fungating mass, necrotic and hemorrhagic in places, protruding fully one-half inch into the cavity and fitting a corresponding depression in the opposite uterine wall. The growth was rather firmly attached to its broad base. A portion of the specimen cut at right angles to the growth and body of the uterus, including both, was reserved for histological examination, and the remainder of the specimen was returned to Dr. Dukeman. The tissue was fixed in Zenker's fluid, hardened in alcohol and mounted in celloidin. Sections were stained in hematoxylin eosin, Mallory's blue, eosin-methylene blue, and phosphotungstic acid-hematoxylin. A description of the sections follows: Commencing at the innermost portion of the growth and lying immediately beneath a thin layer of blood and fibrin are observed numerous remains of chorionic villi, some of which are quite fibrous and others excellently preserved and showing clearly the cellular elements composing them. Between the villi is much granular matter and necrosed tissue which here and there shows definite abscess formation. In other areas clusters of cells, soon to be described, are in close relation to the villi. Not a few of the villi have undergone a hyaline change. A few uterine sinuses are seen which contain blood débris, fibrin, and tumor cells. Blood vessels in this portion are almost wholly absent.

Proceeding outward, the villi disappear and give place to masses of tumor cells, among which masses there is much fibrin. The tumor cells are of two kinds. One variety consists of large, irregular, plasmodial or syncytial masses of deeply staining protoplasm, with large, deeply staining nuclei. Sometimes from two to five nuclei are seen in one mass. The other cells are smaller, irregular to spherical in outline with rather lightly staining, finely granular protoplasm, and containing single, round or oval faintly but distinctly staining, vesicular nuclei (the cells of Langhans). In the masses of cells there are neither blood vessels nor stroma

proper although granular matter, fibrin, and some fibrillary substance between the cells are observed here and there with connective tissue stains. The cell masses have no definite arrangement. There are no traces of glandular structure to be found. At a point where the tumor merges into the uterine wall the conditions are interesting. The growth extends well into the wall in two ways, one by finger like processes which, however, are little in evidence, and the other by the cells dissecting their way beneath the adventia of the blood vessels. Some of the vessels show tumor cells in the lumen. Here and there among the muscle bundles of the uterine wall may be seen both varieties of tumor cells above mentioned. They are observed well out toward the external surface of the uterus. In the external portion of the wall the uterine elements appear fairly normal, but the blood vessels are very numerous, much dilated, and filled with débris. The growth is a chorioepithelioma malignum. Specimen slides accompany this report.

410 Grant Building.

SKIN GRAFTING.*

By ARCHIBALD E. ISAACS, M.D.,

NEW YORK,

SURGEON, BETH ISRAEL HOSPITAL.

Skin grafting is one of the most satisfactory operations in surgery. To us, as physicians, it has lost its novelty, but to the layman it yet appeals as one of the wonders of the surgeon's art. The frequent reports of such cases in the lay press generally include the sensational feature that some relative has volunteered to give part of his skin to the patient. That this practice of using donors to supply the grafts is common is borne out by our knowledge from more reliable medical sources. It was attempted in this case also, and it is one of the points I wish to call attention to.

This boy is ten years old. He came to his injuries in a real boyish way. Playing with his friends at a bonfire, they pulled a paper bag over his head and lit it, and from it his clothing caught fire. He was admitted to the Beth Israel Hospital August 3, 1910, four days after having received his injuries. The hospital chart records a burn of the second degree, extending from his elbow, over the inner surface of the arm onto the chest, which was burned from the midclavicular line anteriorly to the midscapular line posteriorly, and from the first to the tenth rib. He had an acute nephritis and his general condition was such that it called for active stimulation and proctoclysis. At first the usual local treatment was used. On September 28 skin grafting was done, the father acting as the donor. This attempt was not at all successful. I found him in my ward when I came on duty in October, some two and a half months after he had received his injuries. There was but a narrow band of cicatrization surrounding the whole granulating surface. A pyocyaneus infection had persisted from the very beginning and was sufficiently active to stain his daily dressings a dark blue. The whole axilla was bare and the arm was held in flexion to within one inch of the chest. While the original cause for this position was evidently spasmodic muscular contraction for the relief of pain, its persistence had permitted the formation of bands of new connective tissue across the axilla, which now held the arm bound down in this position. On October 24 I took him to the operating room for grafting. As the case was complicated by extension of the wound across the shoulder joint, on its axillary side, cicatricial contraction with loss of function had to be overcome and means taken to prevent its recurrence. In raising the arm, under anesthesia, the axillary bands of new fibrous tissue were torn across and had to be divided further, with the knife, to afford free motion to the joint. The arm was held in extension during the grafting, spreading out the whole axillary surface, and it was subsequently put up in that position, in a plaster of Paris dressing, for the healing. The grafts were taken from the patient's thigh. By the time I had covered the raw surface of his arm and axilla, and an area extending well down onto the chest, about half the denuded surface, I had used up all the available material from one thigh. To get at his other thigh it would have been necessary to change his position on the table, which I feared might displace the grafts, and as the most important part of the work, that involving prevention of

From a photograph taken about three months after skin grafting. Shows tendency to keloidal overgrowth of scar tissue between the grafts; also cicatricial bands across the axilla, which limit extension of the shoulder to about 135°, and which are to be corrected.

cicatricial contraction at the axilla, was done, I decided to leave the balance for a subsequent session. A plaster of Paris jacket, with arm extension, was applied to hold the axillary space open during the healing. Every graft "took," and at the end of a week the surface was healed and dry.

In the alternation of hospital service the boy now came under the care of Dr. H. M. Silver and was referred by him to Dr. Harry E. Isaacs for the completion of the grafting. This was done on November 19, the skin of the opposite thigh being utilized for the purpose. The same method was used as on the previous occasion, all the remaining space was covered, and again every graft "took" perfectly.

In skin grafting it has been my invariable custom to take the material from the patient himself. Most cases where a donor is used could be better done in this way. Instances where sufficient material can not be gotten from the patient must be

* Case presented at the December, 1910, meeting of the East Side Physicians' Association.

rare, as denudation to such an extent, either by burn or otherwise, usually results fatally. The manifest advantage of using the grafts from the patient himself is sparing some other person the anesthesia, the pain and the disability entailed. Other important advantages are the exclusion of the possibility of transmitting infection, and the observed fact that skin from the patient himself is much more likely to 'take." The most desirable part to take grafts from is the outer portion of the thigh, from the knee to the iliac crest. The skin over this region is more firmly attached, and of such structure that it takes the razor edge better than in any other part. One thigh will supply enough for the average case. In this patient both had to be utilized.

The technique used is the following: The wound surface is washed with soap and water and rinsed with saline solution. The part from which the grafts are to be taken is shaved and washed in like manner. Under anesthesia the first procedure is a thorough removal of all the granulation tissue covering the wound. This should be scraped off right down to the white, fibrous, hard, and glistening base. Bleeding is free, but amenable to quick control by pressure with gauze pads wet with warm salt solution. When the area is extensive the hemorrhage in one portion may be thus checked while the next is being scraped. After having gone over the whole surface in this manner the first part is again uncovered, and any remaining shreds of tissue that may have previously escaped notice on account of the bleeding are now cleaned up, and the wet gauze pad replaced for hemostasis. This is obtained by the time the first graft, now to be cut, is ready for placing.

The thigh, previously prepared, is uncovered; an assistant, with his hand on the skin, stretches it in the axis of the extremity. The operator stretches it in the opposite direction with the left hand placed three or four inches from that of his assistant, while with the right he slices off with the razor, previously dipped in salt solution, as thin a layer of epidermis as he possibly can. As the razor advances he slides his left hand along, keeping the skin on the stretch, until some slip of the razor ends that cut of graft or until the desired length is obtained. The cutting is done by an advancing and sawing motion and, as the graft is detached, if properly done and it be thin enough, it folds itself into "accordion folds" on the blade, so that a graft of six inches or more in length will fold up to within a space less than that of the width of the razor blade, across which it will lie. The length of the graft is decided by the size of the area to be covered, the available space to cut from, and the operator's dexterity. The width of the graft is governed by more or less flattening or pinching up of the skin area under the knife by the two hands stretching it. For two good reasons the graft should not be disturbed from its position on the blade until it is finally placed. One reason is that if it be cut as thin as it ought to be its edges will curl up and so badly entangle it that it would be almost a hopeless task to straighten it out again; the second reason is that the simplest and easiest way to place it where it is wanted is to do so directly from its position on the blade. The cutting of a graft that is heavy enough to be handled after removal from the blade has the double disadvantage that it is not so likely to "take," and that it leaves a wound at the site from which it was removed, slow in healing, painful, and scarring in proportion to the thickness of skin removed.

To place the graft the wet pads are removed from that portion of the region to be grafted that was scraped first. The edge of the razor, with the graft folded across the blade, is approximated to one side of the wound and, with a probe, the end of the graft is displaced from the blade and held against the scraped surface while the razor is slowly withdrawn across the wound. The graft unfolds and, as it does, it spreads itself over and adheres to the raw surface. Any tendency to rolling up of its edges, as it unfolds, should be corrected by straightening them out with the probe as the graft falls on the surface during the blade's withdrawal. Air bubbles or blood under the graft should be pressed out. Once placed in this manner the graft will hold its position if not disturbed, and this must be looked out for while subsequent grafts are being cut and placed.

The grafting completed, the surface is covered with strips of gutta-percha tissue, about a half-inch wide, laid parallel to one another and leaving the minutest spaces between, so that any exudate or fluid from the wound can drain into the outer dressings. This is very important, as the stagnation of fluids, generally infected on account of the original condition of the wound, would interfere with the vitalization and union of the grafts. Just as important, again, is the character of the outer dressing. It should be arranged with the view not only of protection of the wound from outside influences, but also to remove, by absorption, the discharges from the wound surface. To assure such absorptive qualities in the dressing it must be put on moist and must be kept moist. Gauze, wrung out of normal salt solution, is laid smoothly over the tissue strips and the moisture retained by covering it with gutta-percha tissue. Over this, with or without a layer of dry gauze or cotton, the roller bandage is snugly applied.

The first redressing is done on the fourth day and is a repetition of the primary one. Subsequent dressings may be done daily or not so often, according to conditions. In the case here reported it was daily on account of the pyocyaneus infection which persisted. The appearance at the first dressing is not very encouraging to the uninitiated. The grafts look macerated and ready to fall off. But at the end of a week it becomes evident that they are vitalized. The bulk of the graft usually does come off, but leaves an epithelium covered surface beneath it. When the surface begins to dry and show its new epithelial covering a dry dressing or a salve dressing may be advantageously substituted for the moist one. The denuded surface left by the cutting of the grafts is treated in a similar manner; that is, by gutta-percha strips laid directly on the raw surface and covered with a wet dressing. This may usually be left on for a week, when it will be found that the surface is practically healed.

1325 Madison Avenue.

Sporotrichosis.—H. G. Adamson reports the case of a man who had lately been in Brazil, where he had got the infection. It was a classical case, with a chain of nodular swellings along the forearm. Numerous cultures of the sporotrichium had been grown from the lesions, and a positive Wassermann reaction, using a sporotrichium culture as the antigen, had been obtained. Several sections of the swellings showed the lesion to be a granuloma with giant cells.—*Proceedings of the Royal Society of Medicine.*

THE CLINICAL STUDY OF FORTY-FOUR CASES OF PNEUMOTHORAX OCCURRING IN THE COURSE OF PULMONARY TUBERCULOSIS.

By JOHN M. CRUICE, A.B., M.D.,

PHILADELPHIA, PA.

PHYSICIAN TO THE HENRY PHIPPS INSTITUTE AND WHITE HAVEN SANATORIUM; INSTRUCTOR IN MEDICINE AT THE UNIVERSITY OF PENNSYLVANIA.

THESE forty-four cases which I am reporting are all the cases of pneumothorax that have occurred at the Henry Phipps Institute from the time of its foundation, February 1, 1903, until February 1, 1910. In the fifth Annual Report of the Phipps Institute Stanton reported twenty-eight of these cases.

Frequency: The frequency of this accident in the course of pulmonary tuberculosis is given by different writers at quite varying figures. Drasche found in 10,212 cases of pulmonary tuberculosis 198 cases of pneumothorax or 1.98 per cent. West reporting on 101 cases of pneumothorax states that 5 per cent. of all cases of phthisis die from pneumothorax. Weil states that of his 55 cases of pneumothorax 46 were due to phthisis. These 46 were from a total number of 1,200 tuberculous cases treated, or about 3.8 per cent. But he thinks that only exact figures can be obtained from cases which come to autopsy. He had 36 cases of pneumothorax in 355 autopsies on persons dying of tuberculosis, or 10.1 per cent.

There have been up to February 1, 1910, 480 autopsies at the Phipps Institute. Of these 480 autopsies, 7 did not show pulmonary tuberculosis. Of my 44 cases, two of them, No. 433 and No. 3,855, were not autopsied, and case No. 889 did not die in the Institute. So in this series of 473 autopsies on cases dying of pulmonary tuberculosis there were 41 cases of pneumothorax, or a frequency of 8.6 per cent.

Sex: All of the writers seem to agree that pneumothorax is much more common in men than in women. In Drasche's series 158 (79.85 per cent.) were men and 40 (20.15 per cent.) were women. Weil's figures were 35 (76.08 per cent.) men and 11 (23.92 per cent.) women. In West's series the sex was specified in 98 cases. Of these 75 (76.53 per cent.) were men and 23 (23.47 per cent.) were women. Morse reported 44 cases, of which number 37 (84 per cent.) were men and 7 (16 per cent.) were women. In my own series 41 (93.18 per cent.) were men and 3 (6.82 per cent.) were women. This gives a larger percentage of men than any series of cases I was able to find in the literature, and is accounted for by the fact that the Phipps Institute had 34 beds for men and only 18 beds for women.

Color: There were 40 (90.91 per cent.) white patients and 4 (9.09 per cent.) negro patients. None of the writers specify the color of their patients, so I could get no figures on this, and none on the frequency of pneumothorax in negroes. My figures are not a fair criterion, as the number of negroes at the Phipps Institute has been much less than the number of white patients.

Age: Of the 44 cases, 18 (40.9 per cent.) were between the ages of twenty-one and thirty, 14 (31.81 per cent.) between the ages of thirty-one and forty, 5 (11.36 per cent.) between the ages of ten and twenty, the same number between the ages of forty-one and fifty, and 2 (4.54 per cent.) between the ages of fifty-one and sixty. The youngest case was fourteen years and the oldest fifty-four. This corresponds with the findings of all the investigators. Morse found 23 (53 per cent.) of his cases were in the third decade, Drasche states that the maximum number of cases were in the third decade, and West says that more than half of his cases were between twenty-five and thirty-five.

Side Affected: It has been stated pretty generally that left-sided pneumothorax is very much more frequent than right-sided pneumothorax. James says that of 85 cases it occurred on the left side in 49 (57.6 per cent.) and on the right in 36 (42.4 per cent.) In Weil's series 31 (67.4 per cent.) were left-sided, 14 (30.4 per cent.) right-sided, and 1 (2.2 per cent.) bilateral. Saussier in 81 cases found it on the left side in 50 (61.7 per cent.), on the right side in 25 (30.8 per cent.), bilateral in 1 (1.2 per cent.) and not stated in 4 (4.9 per cent.). On the other hand Drasche in his series of 198 cases found that 55 per cent. were right-sided. West in 83 cases, where the side was specified, found the left side affected in 42 (50.6 per cent.) and the right side in 41 (49.4 per cent). Emerson in his series of 22 cases had 11 (50 per cent.) on each side. Of the 41 cases that were autopsied at the Phipps Institute, 24 (58.8 per cent.) were left-sided and 17 (41.2 per cent.) were right-sided.

Cause of Onset: The cause of onset was given in only seven cases in my series. In five of them the pneumothorax developed during a fit of coughing. One case developed it on account of the exertion put forth in going up-stairs and the other one was seized while straining at stool. In Drasche's series of 30 4 followed coughing, others followed straining at stool, vomiting, lifting heavy loads, and one resulted from turning over in bed. Crowdy also cites a case where pneumothorax developed in a tuberculous man when turning over in bed.

Onset: Osler states that "the onset is usually sudden and characterized by severe pain in the sides, urgent dyspnea, and signs of general distress. There may, however, be no urgent symptoms particularly in cases of long standing phthisis." In the 30 cases of the series I am reporting, in which the onset was recorded, it was acute in 23 (76.6 per cent.) and gradual in 7 (23.4 per cent.). Thirteen of the 23 cases with acute onset had records of dyspnea and pain in the affected side, 4 had dyspnea but no pain, 3 had dyspnea but no record of pain, one right-sided case (No. 3,855) had dyspnea and pain in the left side. Case No. 6,116 complained only of marked palpitation and had no dyspnea and no pain. Case No. 6,171 had marked dyspnea with an expiratory grunt but had no pain. Nine of the cases showed more or less signs of shock. In the 7 cases with a gradual onset, after the establishment of the pneumothorax, 4 complained of pain and dyspnea and 2 of dyspnea alone and in one the symptoms were not recorded. It is in these cases of gradual onset, occurring in advanced phthisis where there is already a certain amount of dyspnea and general debility, that the condition is liable to be overlooked.

Previous Lung Condition. The study of the lung condition previous to the development of the pneumothorax is interesting, but does not seem to be particularly instructive. All these cases had advanced tuberculosis running an acute course; the temperature in some of them going as high as 104°

*Read before the Section on General Medicine of the College of Physicians, Philadelphia, April 24, 1911.

F., and in all of them above 100° F. In the right-sided cases the clinical findings were recorded in nine cases. All of these had in the right lung cavities in the upper lobe, two in all three lobes, and one in the upper and middle lobes. In the lobes where no cavities were recorded there was more or less infiltration except in one case where the middle lobe gave no abnormal signs. The left lung in these right-sided cases was almost as much involved as the right. In only one case was the whole lung free of involvement. In the upper lobe of six cases there was cavity formation, one showed it in both upper and lower lobes. The other two cases had more or less infiltration. The left-sided cases

in which the clinical findings, before the development of the pneumothorax, were recorded showed approximately the same relative condition, advanced tuberculosis in both lungs with the condition a little more marked on the left side. Weil states that he never saw pneumothorax develop in a non-febrile case of tuberculosis. He also states that he had found that it developed on the side with the most advanced tuberculosis in 74.3 per cent. of the cases. West says: "It may be stated that as a rule the liability to the affection is greatest in the rapidly advancing cases, that is in those where the pleural adhesions have not had time to become firm, and as a corollary of this it follows that pneumothorax

does not always occur upon the most affected side."

Decubitus: James says: "As a rule the patient lies most comfortably on the opposite side, but occasionally the knee-chest position is preferred, while sometimes a sitting or half-sitting posture gives most relief." Rosenbach says, "the patient tends to assume an erect position and usually protrudes the healthy side somewhat so as to diminish the circumference of the diseased half of the chest." Emerson states "as a rule the patient prefers to lie on the affected side." The decubitus was recorded in 24 of my cases. In 7 the patients lay on the affected side, and in the same number of cases they lay on the unaffected side. In 4 cases the patients lay flat on the back and in 3 sat in an erect position. In 2 instances they lay on either side, one, however, assumed a semi-reclining position. It may fairly be stated that there is no fixed decubitus in pneumothorax, but that the sufferer assumes the position in which he has the greatest ease, and this position varies greatly in different cases.

Enlargement of the Affected Side: In 31 cases in which the size of the affected side was noted it was enlarged in 24 (77.4 per cent.) and not enlarged in 7 (22.6 per cent.).

Motion of Chest: In 33 cases in which the motion of the affected side was noted it was diminished in 26 (78.48 per cent.), absent in 3 (9.09 per cent.), good in 3 (9.09 per cent), and increased in 1 (3.03 per cent.).

Fremitus: In 24 cases in which the tactile fremitus was noted it was decreased in 12 (50 per cent.), absent in 9 (37.5 per cent.), increased in 2 (8.3 per cent.), and normal in 1 (4.2 per cent.). James states in 70 cases of his, in which the fremitus was noted, it was diminished in 52 (74.3 per cent.) and absent in 18 (25.7 per cent.). Nothnagel says that tactile fremitus is not absent, only diminished.

Percussion: In 39 cases in which the percussion note was recorded it was hyperresonant in 32 (82.05 per cent.), tympanitic in 5 (12.82 per cent.), dull in 1 (2.56 per cent.), and normal in 1 (2.56 per cent.). These findings correspond with the statements of a great number of the writers. Osler says, "the resonance may be tympanitic or even have an amphoric quality. This, however, is not always the case. It may be a flat tympany or it may be a full hyperresonant note, while in others it may be dull." Movable dulness was noted in 24 of the cases, being present in 7 (28.75 per cent.) and absent in 17 71.25 per cent.).

Vocal Resonance: In the 27 cases in which vocal resonance was recorded it was increased in 10 (37 per cent.), decreased in 6 (22.2 per cent.), and absent in 11 (40.8 per cent.).

Breath Sounds: In the 38 cases in which the breath sounds were recorded they were absent in 7 (18.42 per cent.), feeble or distant in 20 (52.63 per cent.), amphoric in 6 (15.78 per cent.), cavernous in 3 (7.89 per cent.), and bronchovesicular in 2 (5.26 per cent.). Of the cases with feeble or distant breathing some were qualified as distant bronchial, one as distant cavernous, and one as faint vesicular. Most of the authorities state that the breath sounds are usually absent or distant, or of an amphoric quality.

Râles: The presence or absence of râles was noted in 32 cases, occurring in 15 (46.9 per cent.) and absent in 17 (53.1 per cent.).

Pectoriloquy: In the 28 cases in which pectoriloquy was noted it was present in 5 (17.86 per cent.) and absent in 23 (82.14 per cent.).

Coin Test: The coin test was recorded in 32 of my cases and was present in 29 (90.6 per cent.) and absent in 3 (9.4 per cent.). This sign can be considered almost pathognomonic of pneumothorax although Osler has reported a case where it was obtained over a large cavity, and it is said to be found at times over a dilated stomach. Stanton says, "special peculiarities regarding the finding of the coin test must be borne in mind. It may not appear for the first day or so after the pulmonary rupture occurs. It may be present only when the patient is placed in a certain position. One is not justified in saying the coin test is absent unless the patient has been examined both sitting up and lying down. When recumbent the patient should be made to lie on the side and the coins and the stethoscope placed in every possible relationship to each other before a negative finding is recorded."

Succussion Splash: In 19 cases in which the succussion splash was recorded it was present in 6 (31.6 per cent.) and absent in 13 (68.4 per cent.). When present it is one of the most valuable signs we have for diagnosing pneumothorax. A rather similar sound is said to occur under certain circumstances in the stomach or intestines, and also in large cavities. With care these conditions can as a rule be excluded.

Metallic Tinkle: Metallic tinkle was present in 7 (38.88 per cent.) of the 18 cases in which it was recorded and was absent in 11 (61.12 per cent.). This also is a most valuable sign. James in his series of cases found it in a much larger percentage. It was present in 30 (85.7 per cent.) of his 35 cases in which it was recorded.

Displacement of the Heart: In the 31 cases in which the position of the heart was recorded it was found displaced in 29 (93.55 per cent.) and not displaced in 2 (6.45 per cent.). In one of these two cases it was found at autopsy that the pleural cavity on the side of the pneumothorax was completely obliterated from the apex down to the fourth rib by firm adhesions; below this was a pyopneumothorax with the air under only slight pressure. Morse found the heart displaced in every case but one in his series.

Displacement of the Liver: In the 8 right-sided cases in which the position of the liver was noted it was found displaced in 7 (87.5 per cent.) and not displaced in 1 (12.5 per cent.). In the 10 recorded left-sided cases it was found displaced in 1 (10 per cent.) and not displaced in 9 (90 per cent.).

Duration: In the 38 cases in which the duration of the cases was recorded (7.9 per cent.) died in less than twenty-four hours, 11 (28.9 per cent.) in less than a week, 6 (15.8 per cent.) in less than a month, 7 (18.4 per cent.) in less than two months, 3 (7.9 per cent.) in less than three months, 4 (10.5 per cent.) in less than four months, 2 (5.3 per cent.) between the sixth and seventh month, 1 case (2.6 per cent.) lived ten months, and 1 (2.6 per cent.) lived for fourteen months. The shortest duration was two hours. West says that 75 per cent. of pneumonothorax cases die within the first fourteen days and about 90 per cent. before the end of the first month. These figures are considerably higher than mine. In the first two weeks 42 per cent. of the cases died and within the first month only 52.6 per cent. of the cases died. Weil also found that one-half died in the first month.

Conclusions.—1. Pneumothorax occurs in the course of pulmonary tuberculosis in from 5 to 10 per cent. of all cases.

2. It occurs more frequently in men than in women.

3. It occurs most frequently between the ages of twenty and forty, at the time when phthisis is most fatal.

4. It probably occurs with equal frequency on either side.

5. The patient may assume any decubitus. Without reference to the side affected, he chooses the position in which he has the greatest comfort.

6. In the majority of cases the percussion note is hyperresonant, although tympany, dulness, or resonance may be found.

7. The breath sounds are usually absent or distant. The distant breath sounds may have any quality. In some few cases amphoric or cavernous breathing may be heard.

8. The most diagnostic signs of the condition are the coin test, displacement of the heart and, in right-sided cases, displacement of the liver. These signs occur in about 90 per cent. of the cases.

9. The succussion splash and metallic tinkle are most diagnostic but are found in a comparatively small number of cases, about 30 to 40 per cent.

10. Pneumothorax is a most grave condition. At least 50 per cent. of the cases die within the first month. Occurring in advanced tuberculosis, it is always the beginning of the end.

1815 Spruce Street.

NEUROPATHIC JOINT DISEASE.*

By L. S. MANSON, M.D.,

NEW YORK.

The affections of the joints that we meet with in diseases of the nervous system may be divided into those of hysteria, locomotor ataxia or tabes, and syringomyelia. I will not include the very intense and exquisite spinal tenderness of the hysteric, nor the painful sensations experienced by her half-sister, the neurasthenic, which may be felt anywhere along the vertebral column but most frequently only over the lower cervical, sacral, or lumbar region (which painful sensations are very similar to those that constitute their headaches and consist of a pressure, dragging, heat, or burning) because these pains do not indicate any involvement of the vertebral joints proper, are rather superficial in the majority of neurasthenics, are not intesified by deep pressure, and, in the hysteric, frequently become tolerant on deep and vigorous pressure if the patient's attention can be completely distracted.

Hysteria is the most common of all chronic diseases, and there is no affliction known to mankind that this protean malady cannot simulate. For instance, I have seen hysterical temperatures of 105° and 106° during most critical periods such as childbed, when I experienced some very anxious moments before arriving at a proper diagnosis, and more than once have I been asked by physicians to corroborate a diagnosis of brain abscess or brain tumor, when the condition proved to be nothing but hysteria. Many an hysterical girl has been mutilated and robbed of her healthy appendix simply because in addition to her hallucination of pain in the right side she displayed some elevation of temperature for a week or so. The most favorite joints it selects for its manifestations are the knee, elbow, wrist, and ankle, and it shows itself in three distinct forms, the main characteristics of which depend on some disturbance of the nervous system producing symptoms identical with, but unaccompanied by, structural changes or pathological lesions.

In the first variety we have pain in the joint of a most intense and excruciating character, too intense to correspond to any known organic lesion, out of all proportion to other signs of disease, without local evidences of inflammation, aggravated on the slightest manipulation, but frequently, however, displaying tolerance on deep pressure, if the patient's attention be distracted. Starr records an instance of hysterical pain in a knee-joint which kept a patient in bed for three years and appeared in the other knee when the leg was amputated as a last resort.

In the second variety we have rigid immobility due to persistent muscular spasm, and in the third variety we have inability to move the joint due to muscular paralysis. Here we have no pain, the electrical reactions are normal, there is not much wasting, and in reality we are dealing only with a nervous disorder involving the muscular system which indirectly produces a rigid or powerless joint. The spasmodic rigidity and contracture are most intense—more than is obtained in contracture from organic disease and, unlike the latter, becoming even more intense upon any attempt to correct or overcome the same.

The paralysis, likewise, is most complete—more so than obtains in organic disease—and, unlike what is noted in the latter, the patient does not even attempt to move the powerless limb, owing to the existing abulia or complete loss of will power. The patient invariably says "I cannot"; she should say, "I will not," or better still, as Sir James Paget aptly put it, "I cannot will."

The diagnosis in these cases is not difficult when in addition to the characteristic features above mentioned one takes into consideration the etiology, the neuropathic heredity, the hysterical temperament, including the vivid imagination, suggestibility, impulsiveness, desire for sympathy, emotional instability, and, above all, the various hysterical stigmata, particularly the insensitive throat and eye-ball, the zones of anesthesia or hemianesthesia, and the contraction of the visual and color fields.

The urine generally shows a reduction in total solids, especially in urea and phosphates, with the proportion of alkaline and earthy phosphates inverted. The knee-jerk is invariably exaggerated unless there is an accompanying multiple neuritis or locomotor ataxia. Before making a positive diagnosis, however, I must strongly urge the necessity of eliminating all possibility of a coexisting organic lesion, for not infrequently we find hysterical and organic disease of the joint combined. In this connection, I might mention the case of Jennie S., who came to us from one of our large hospitals, where the orthopedist and the neurologist expressed different views, but who showed unmistakably the coexistence of hysteria with a spastic paralysis due to a lateral sclerosis of the cord. This 14-year-old girl, as was to be expected, is now helpless and bedridden.

As to treatment we must bear in mind that we are dealing with a mental disorder which must be treated mentally and our sheet anchor must be, aside from attention to the general health, suggestion and persuasion; and in order to produce the

*Read at the clinical meeting of the Hospital for Deformities and Joint Diseases, May 23, 1911.

best possible results we must employ indirect as well as direct suggestion. The patient must be accompanied to the consultation room by a relative or attendant (a rule which for obvious reasons I cannot insist upon too strongly); and after making a few painful applications of the electric current to the joint or limb we should address the attendant, speaking in an undertone, presumably for the patient not to hear, but loud enough to make sure she does hear, stating that from all indications, such as the general appearance, the improved blood state, etc., a cure is gradually, but surely, taking place, and that the patient will be thoroughly well in even less than the allotted time for a promised cure.

We now come to two most interesting, though gloomy, conditions—the arthropathies of locomotor ataxia and syringomyelia, and I will speak of them conjointly for the reason that they have much in common. In 1868 Charcot first described the joint affections accompanying locomotor ataxia, hence the appellation Charcot's joint. Etienne, as far back as the latter half of the sixteenth century, first described the post-mortem findings in the spinal cord, which we now recognize as belonging to syringomyelia, but it was not until 1887 that Schultz and Kahler gave a good clinical picture of the disease which made the diagnosis possible.

In tabes the joints become affected in from 2 to 4 per cent. of the cases, while in syringomyelia fully 10 per cent., and, according to some authorities, as high as 33 per cent., show affections of the joints. In tabes in between 75 and 80 per cent. of the cases the joints of the lower extremities are involved, and in syringomyelia those of the upper limbs are involved in a similar proportion—a fact easily accounted for by the lesion involving primarily the lumbar segments of the cord in the former and the cervicodorsal segments in the latter. In syringomyelia the joints of the spine are frequently affected, giving rise to deviations of the vertebral column in the nature of a scoliosis or even angular deformity. Some of the cases of scoliosis, however, are due merely to the extensive wasting of the spinal muscles on one side. In tabes the joint affection may precede the onset of the cardinal symptoms of that disease. These are (1) loss of knee-jerk, (2) Argyll-Robertson pupil (insensitive to light but sensitive to accommodation), (3) lightning pains, and (4) ataxia or muscular incoordination. Of these the loss of knee-jerk is probably the earliest and most constant symptom.

The cardinal symptoms of syringomyelia are (1) thermoanesthesia or loss of temperature sense, (2) analgesia, and (3) progressive muscular atrophy, beginning in the small muscles of the hand and extending upward and to the spine. The changes in the joints are practically identical, which is, undoubtedly, accounted for by the similarity of the essential nature of the nerve lesions. In tabes we have primarily a degeneration of the sensory tracts —the posterior nerve roots, posterior columns, and horns, the disease process extending from without inward; while in syringomyelia we have a dilatation of the central canal with gliomatosis producing a secondary degeneration in the same nerve structures, the disease process extending from within outward.

The tabetic anesthesia and syringomyelic analgesia produce a loss of nutrition in the joints due to the absence of reflex stimulation and account for the similar nature of the arthropathy.

In nearly all the cases we find an abnormal range of joint motion, an almost complete absence of pain, and an enormous swelling extending to the adjacent parts, frequently of rapid or sudden onset, and without any local evidences of inflammation. Within the joint we find the capsule dilated or ruptured; a large collection of synovial fluid; the synovial membrane thick, rough, adherent, or destroyed; the ligaments soft, elongated, and loosened from their attachments; the cartilages become destroyed, the bone surfaces become absorbed and creak on motion, the erosion in some instances extending to several inches of their length. In some cases a hypertrophic form of arthritis deformans takes place, and in still others both varieties may be combined.

The subject of treatment I will relegate to my more optimistic colleagues, the orthopedic surgeons.

616 Madison Avenue.

ARTERIOSCLEROSIS.

By WILLIAM FRANCIS WAUGH, A.M., M.D.,
CHICAGO, ILL.
PROFESSOR OF THERAPEUTICS, BENNETT MEDICAL COLLEGE.

Hardening of the arteries has long been considered the essential characteristic of those changes that constitute old age. "A man is as old as his arteries," is true, truer than that he is aged according to the years he has lived. Indeed, it was probably the obvious fact that some men are physically older than others who have lived just as long, that directed the attention of men to the study of the physical causes of senility.

The morbid process in the arteries commences with irritation by some abnormal substance in the blood. This induces contraction, narrowing of the lumen of the vessels, necessitating the expenditure of more power by the heart to force the blood through the narrower outlets. Hypertrophy of the heart follows, with an increase in the pressure upon the arteries nearest the heart, where the increase of force is first felt. The result is a development of resistance in the arterial walls, with the anatomical changes well known. But what occasioned the first step of the chain of morbid processes?

We are confronted with a condition so common to the aging as to be held characteristic of senility, yet not necessarily present at any age, and much more marked in some cases than in others. We should seek for a cause common but not universal at this period of life, and for certain exceptional causes affecting some individuals but not very many.

The first, general, cause we find in that decline in the sensibility and the motor power of the colon, incident to advancing age. Fecal matter collects in the large bowel, and is retained beyond the normal period. There are no such safeguards here as in the small intestine and decomposition goes on unchecked. Toxins are developed which are absorbed into the blood, where they irritate the walls of the vessels through which they circulate. Here we have an adequate general cause, one whose presence and capability of inducing the first lesions are not questioned. It is not a difficult matter to demonstrate: Take the urine of any man over fifty years of age, and with Harrower's indicanmeter you may demonstrate the presence of indican, derived from feces, circulating in the blood, and excreted by the kidneys. There are clinical tests

quite as satisfactory. Senile pruritus is invariably dependent on fecal toxemia, and if affecting the anal region, it attends acidity and pyrosis. Dry, brittle nails and a scaly skin frequently accompany this condition. Pyorrhea alveolaris has recently been recognized as due to the same cause. Early loss of the hair may be an evidence of superior mentality, as has been asserted, but it is curiously frequent in the victims of autotoxemia. I do not wish to intimate that indican is the agent of these alterations. Acidemia will, I am confident, prove to be the most common pathogenic element, but indican furnishes the most readily available test for the general condition.

Of the accessory causes that determine the early or more pronounced forms of arteriosclerosis, we have the other maladies that may contribute toxic irritant elements to the blood. Among these we may enumerate gout, rheumatism, and those forms of indigestion that contribute acids to the blood; gonorrhea and suppuration—possibly dental caries—that supply bacteria or their toxins; syphilis, malaria, and other maladies furnishing protozoa; the metallic poisons, lead, arsenic, mercury, etc., and probably others as yet undetected. The influence of alcohol seems positive, yet this is rarely present without the concomitant influence of one of the other causal conditions enumerated. Whether tobacco causes arteriosclerosis I must be permitted to question. It is so purely a relaxant that its influence seems to counterbalance that of the irritants; it favors elimination, and if not used excessively has been found to be apparently innocuous even when continued to extreme old age. Those who seem to be injuriously affected by even moderate quantities of tobacco are the rather rare exceptions among men. All we can justly claim against tobacco now is that it should not be used by those to whom it is evidently injurious. But it should be the physician and not the patient who decides this.

There is no sufficient evidence for placing sexual indulgence among the causes of arteriosclerosis. Long-continued physical exertion, beyond the physiological limit of the individual's capacity, may induce atrophic and hypertrophic alterations in the muscular fibers of the arterial coats as well as in the skeletal muscles; but here also we recognize the action of the chemotaxis.

The treatment is deducible from the etiology. Keep up the activity of the large bowel. Study in each case the effect of various remedies for this purpose, and suit the individual peculiarities. Do not give simply "a" laxative or cathartic, but ascertain which is "the" one for this patient. Aloin acts most powerfully on the rectum, cascara on this and the descending colon, senna on the cecum and ascending colon. The latter wears out, if continued, sooner than either of the others. If the dose is exactly enough, and the patient resists the impulse to create an artificial diarrhea, aloin or cascara may be continued for years with undiminished efficacy.

Combinations are better than single remedies if made purposefully; the action is smoother, more uniform, with less stimulation of a single function. A morning dose of a saline laxative, such as sodium sulphate or phosphate, a scruple of either in a glass of water on rising, will often suffice. But the occurrence of a daily evacuation does not mean an emptied bowel, and the indican test should be employed regularly. As the disease advances the colonic enema must be brought into requisition.

Attention to diet is of prime necessity. Raw prunes are very useful. All fruits are laxative. The food supply must be carefully restricted to the needs and any excess of nitrogen forbidden. Yet, as "man is prone to evil as the sparks to fly upward," as the digestive powers decline, the easily digested meats that yield a quick return in assimilable nutriment, are apt to be preferred, unconsciously.

The use of sour milk, as advised by Metchnikoff, deserves especial study. Very often it is particularly relished, or even craved by these patients; and for this there is a physiological cause. Since commercial pasteurization has become general, destroying the protective enzymes and lactic acid generators, allowing the putrefactive organisms to multiply unchecked and the ptomaine formation to go on without the warning of souring, the use of all forms of milk has become more perilous. This favors the use of the Bulgarian bacilli, provided the preparations can retain these indefinitely in an active condition.

Nearly everybody who believes in the value of drugs in treating arteriosclerosis recommends some form of iodine. Personally, my best results have followed the use of arsenic iodide, in doses of a milligram before meals and at bedtime; increased to seven daily doses, or until irritation of the eyelids betokens the beginning of toxic action, and then held as closely as possible to that point without quite touching it. This treatment has been maintained for six, twelve, and eighteen months, with very satisfactory results. Arsenic iodide is an effective gastroduodenal antiseptic, stopping fermentation there; it stimulates absorption and elimination and carries the liquefied metallic and other toxins out of the system. With proper regulation of the diet and the bowels, it is effective.

When vascular tension is marked veratrin offers advantages to be secured from no other remedy. By its judicious use the arterial tension may be moderated at will, and maintained at the normal point for months or years, without a trace of harm, immediate or remote. It is not a mere symptom remedy, for while thus controlling the vascular tension it is stimulating all the eliminants to excrete the toxins that are working the evil. No form of nitrites is suitable for such continuous relaxation. Their place is where quick and brief effects are desired. The textbook dosage of veratrin is erroneous, because it was not fixed by those who had had wide experience in the internal use of this remedy. Of the pure alkaloid veratrin, the average adult dose is half a milligram, given in at least two ounces of water, and repeated every one to four hours until the desired effect has been secured. The dose thus ascertained may be divided into three portions and taken in the usual way, after meals. The advantages of this remedy are its uniform and certain effect, easily maintained, and its absolute safety, since under no circumstances can harm occur when it is administered as here suggested. It provides its own elimination, so that remote ills or cumulative perils are impossible.

It has been twenty-five years since I settled upon this treatment of arteriosclerosis. As may be inferred, my own age is such as to render the malady of some personal interest. Sufficient time has elapsed to permit a fair judgment of the results, in an affection where the prolongation of active, use-

ful, enjoyable life is the test of efficacy, and autopsies aid only by their absence. Judging by the clinical data, I feel warranted in recommending the treatment herein outlined to my colleagues.

1358 Fulton Street.

SOY BEAN COOKERY.

By JOHN RUHRAH, M.D.,

BALTIMORE.

The soy bean (*Glycine hispida*) sometimes referred to as the soja bean, is an annual leguminous plant which has been cultivated from very earliest times, especially in Japan and China, and in these countries it has been used for food since long before the time of Confucius. Although one of the chief articles of diet in these countries, its use has been very slow in spreading to other lands. In China and Japan the bean is utilized as a food in a great many different ways, a fact to which I have already called attention in previous publications.*

There are variations in the composition of the different varieties of beans. The yellow beans grown in America have the following composition:

Water	10.14	per cent.
Protein	34.63	per cent.
Fat	17.98	per cent.
Nitrogen free extract	30.50	per cent.
Fiber	3.69	per cent.
Ash	3.07	per cent.

Calculated to a water free basis:

Protein	38.50	per cent.
Fat	20.	per cent.

The soy-bean flour has the following composition:

Proteins (N x 6.25)	44.64	per cent.
Fat	19.43	per cent.
Mineral matter	4.20	per cent.
Moisture	5.26	per cent.
Crude fiber	2.35	per cent.
Cane sugar	9.34	per cent.
Non-nitrogenous extract	14.78	per cent.
Starch	None	
Reducing sugars	None	
Polarization normal weight due to optically active substance other than cane sugar included in proteids and non-nitrogenous extract	7.86°	

Egasse first suggested the use of the bean in the diet of various diseases, particularly in diabetes, and the first trials in this disease were made by Dujardin-Beaumetz at the Cochin Hospital in Paris.

Since publishing the articles referred to above, I have had so many requests for information about the preparation of the soy bean, especially for diabetics and also for its use in other diseases, that I thought it best to bring together a few of the methods of preparation which have been used with success. It may be noted that the soy bean flour yields about 13 grams of protein and has a food value of about 120 calories.

In diabetes the beans may be added to the diet simply to give variety, and they may also be used to great advantage in connection with an otherwise carbohydrate-free diet, particularly in those cases in which the sugar percentage is high, and it is with these cases we have had particular success.

The simplest way to use the beans is to cook them like the ordinary navy bean, preparing either bean soup, boiled beans, or baked beans, the flavor usually being rather improved by the addition of a piece of fat salt meat. It is also a good plan to soak the beans for eight or ten hours, stir them up, and remove the rather firm envelope which encloses them, most of which will be found to come to the surface, from which they may be easily skimmed off. The beans may be boiled and reduced to a smooth gruel and used in this way as a gruel, although this is rather a troublesome process, or the beans may be thoroughly boiled and mashed and may be flavored with some other vegetable, particularly stewed tomatoes. The soy bean flour may be utilized in many ways.

Archives of Pediatrics, July, 1909; *Journal of the American Medical Association*, July 10, 1909, p. 140; *American Journal of the Medical Sciences*, December, 1910.

Gruels.—A quart of gruel is made by boiling from 1 level tablespoonful to 6 ounces of the soy gruel in one quart of water for fifteen minutes, adding water to make up for loss by evaporation. Salt should be added to taste.

	Protein.	Fat.	Carbohydrates.
1 level tablespoonful to quart	0.35	0.15	0.08
1 ounce 4 tablespoonfuls to quart	1.40	0.60	0.30

These gruels do not thicken during cooking, as they contain no starch, and readily settle on standing. This may be overcome by adding 1 to 2 heaping teaspoonfuls of barley, oat, or wheat gruel flour before cooking, which will add 0.6 per cent. to 1.2 per cent. starch to the gruels, and also slightly increase the percentage of protein.

Broths.—Add 1 to 8 ounces of the flour to 1 quart of beef, mutton, veal, or chicken broth and boil for fifteen minutes, adding water to make up for loss of evaporation; or, boil the same quantity of the soy flour for one hour with one quart of water, to which has been added a piece of ham, bacon, or salt pork to give flavor. Each ounce of the flour will add to the broth about 13 grams of protein and 120 calories, or in percentage add 1.4 per cent. protein, 0.60 per cent. fat, and 0.30 per cent. carbohydrates. A broth made with 6 ounces of the soy flour to the quart would be half as rich in protein and fat as steak.

Muffins.—To make muffins from the soy flour, take 1¼ teacupfuls of the soy flour, ¼ teacupful of wheat flour, ½ teaspoonful of salt, 2 eggs, 1 teacupful of sweet milk, 2 rounded teaspoonfuls of baking powder, and 1½ tablespoonfuls of melted but not hot butter. Beat well together, adding the melted butter last, and bake in gem pans in a hot oven. This will make about twelve muffins which will contain about 150 grams of protein, and which will yield about 1,800 calories, of which the carbohydrates produce but 280. Inasmuch as the soy flour contains no starch, the addition of some wheat flour in making muffins is required. The mixture of wheat and soy flour in this formula will contain about 36 per cent. protein and 20 per cent. carbohydrates, against 14 per cent. protein and 60 to 70 per cent. carbohydrates in gluten flour. The proportion of protein to carbohydrates is eight to ten times as large in the mixed soy and wheat flour as in gluten flour.

In addition to these methods, the following recipe for muffins has been suggested by Dr. Skinner of New Haven, Conn.: Soy bean flour, 1½ cupfuls; salt, ½ teaspoonful; baking powder, 2 even teaspoonfuls. Mix well and add 2 tablespoonfuls of cream which has first been thoroughly stirred into a cup of cold water. Add 2 eggs and beat together. Then add 2 tablespoonfuls of melted butter and beat the whole mixture well together. Bake 15 minutes in a heated gem pan. The above makes 15 muffins.

Another recipe for muffins is to beat up 3 eggs, add 1 cup of milk, in which 1 grain of saccharin has been dissolved, and a lump of butter the size

of an egg. Enough of the bean flour should be added to make a batter with ½ teaspoonful of baking powder. This should be baked in buttered muffin pans.

Nut-cakes.—These may be made by using the above muffin recipe as a basis and adding chopped nuts, almonds, or any other kind desired; and the flour is improved by the addition of a small amount of spice.

Soy Bean Cakes.—These may be made by taking 1 tablespoonful of cocoa, 1 teaspoonful of cinnamon, 1 teaspoonful of allspice, and chopped nuts, adding them to the batter as prepared for the muffins.

Breakfast Food.—As a breakfast food it may be utilized by taking 1 cup of flour, enough milk or water to moisten it into a paste, a pinch of salt, and 1 grain of saccharin, which should be dissolved before adding. Boil 1½ hours in a double boiler and serve with rich cream.

Pancakes.—These may be made by beating up 2 eggs with a pinch of salt, adding enough meal to make a batter, and ¼ teaspoonful of baking powder. This should be fried with butter and made into small cakes.

Soy Bean Cheese.—In China and Japan the bean is used chiefly in the form of a cheese-like substance, the most common forms of this being natto, tofu, miso, yuba, and shoyu. These cheeses are eaten daily by almost all the inhabitants of the East, but they are said to have a lack of flavor that renders them more or less unsuited for European and American palates. In Seattle, Wash., and other places in the West, I am informed that tofu is made by the Japanese and sold to the Oriental residents. I have not had any personal experience so far with the bean cheeses, although they are evidently very easy to manufacture. One may be made from the gruel, which resembles somewhat curds and whey, but which in the only form I have tried is not sufficiently palatable for use, although very slight flavoring might make it a valuable food for American use.

The following suggestions for cooking the bean are made by Goff:*

Grilled Soy Beans.—The beans may be grilled like chestnuts, using the same method. If the beans are old and dry they should be first soaked in warm water.

Soy Beans with Butter.—Let the beans soak in warm water until the hulls are separated and float upon the surface, then let them strain for 24 hours, when they should be cooked, according to the age of the grains, from 1 to 4 hours, and seasoned to taste. They should then be strained again and served hot with butter on lettuce or romane.

Soy Beans au Gras.—Place a chopped onion in a casserole of fat and fry it until the onion becomes brown. Then add the soy beans cooked as above, and allow them to cook a few minutes longer.

Bread or Cakes of Soy Beans.—Triturate in a mortar 250 grams of soy flour with two fresh eggs and a large spoonful of milk. When this is perfectly mixed, add a pinch of baking powder, place in well-buttered molds, and cook from 15 to 20 minutes. This may be flavored with vanilla, orange flowers, or with pieces of citron. They may be divided into small cakes and then cooked in very small molds.

839 North Eutaw Street.

*Gazette des Hôpitaux, March 7, 1911, p. 399.

The Source of Bile Pigment.—Brugsch and Yoshimoto produce what they believe is absolute proof that bile pigment is derived from hematin.—*Zeitschrift für Experimentelle Pathologic und Therapie.*

Practical Treatment of Congenital Talipes Varus Equinus.—M. L. Lamy advances a new method of operative treatment of talipes equinovarus in the infant. When the deformity does not yield to massage during the first three or four months of life it may be considered irreducible. Operation of some kind becomes necessary. Tenotomy is satisfactory only in muscular cases. When the deformity is ligamentous or osseous it is insufficient. The various bony operations that have been proposed either shorten the foot, or give a bad appearance and gait, or destroy the motion of the ankle and foot joints, or leave adduction and rotation of the foot. The operation that is proposed by the author involves a subcutaneous removal of the osseous nodules of the astragalus, cuboid, and calcaneum, leaving the cartilaginous shell and the periosteum intact. The foot is then reduced and made malleable by movements of severe massage, and is immobilized in the correct position with plaster. After three weeks in bed the plaster is removed, and a fresh massage under general anesthesia given, with measurements for a brace which will raise the point of the foot and external border. Plaster is worn another three weeks and the child is then allowed to walk with the brace on. This apparatus is worn for two years, with frequent massage and voluntary exercises of the foot. The author claims that there are none of the inconveniences of the other methods and that this procedure preserves the advantages of all the others. There is no shock, no infection, no hemorrhage, no sutures, no cicatrices. It allows of complete reduction of the deformity without mutilation, and with preservation of the articular surfaces and the movements of the joints. It preserves the length of the foot and the elements of growth. It allows of acting upon the principal factor of the deformity, that is the bones themselves.—*Gazette des Hôpitaux.*

Auricular Troubles in the Course of Treatment of Syphilis by Organic Arsenical Products.—H. Gaucher and H. Guggenheim state that some of the new arsenical products used in the treatment of syphilis have been responsible for deafness in a number of cases. This disease, accompanied by tinnitus aurium is caused by a toxic condition due to the effect of the arsenic on the auditory nerves. Atoxyl has a very bad effect on the optic nerve; so has arsenophenylglycin. Arsacetin produces degenerative lesions of the vestibular nerve. Hectin has been responsible for deafness in two cases related by the authors. Bilateral deafness appeared suddenly, and examination showed that it was the labyrinth that was affected, especially the cochlear nerve. These affections come on as soon as doses of over three grams and a half have been given uninterruptedly. Hence we should be careful as soon as this dose is approached, and as soon as any symptoms are observed the dose should be diminished. As to the use of arsenobenzol numerous observations have been published of deafness occurring during its administration. Still there are a number of cases of syphilis that when untreated produce deafness. The authors believe that they can show that there are more cases occurring with than without the use of arsenobenzol. They appear during the first four months after the injections have been made; there is a lesion of the auditory nerve and it may be associated with a neuritis of the facial or optic nerves. It is the cochlear branch that is involved, and sometimes the vestibular branch. The bony conduction is lessened and acuity of hearing is lessened on both sides. There may also be vertigo. The condition undergoes retrogression as soon as the remedy is stopped and the prognosis is good for hearing.—*La Presse Médicale.*

CYTORYCTES VACCINÆ.

CELL-INCLUSIONS in the Malpighian layer of the skin removed from patients suffering from smallpox or vaccina were seen and interpreted as protozoa as early as 1887 by Pfeiffer, but he had found protozoa in so many diseases that little attention was paid to the observation at that time. In 1892, however, Guarnieri inoculated the corneal cells of rabbits and guinea-pigs with vaccine virus and with pustule contents and found that the peculiar cell inclusions reappeared in each new epithelium inoculated. He regarded them as protozoa, naming them *Cytoryctes vaccinæ* and *Cytoryctes variolæ*. In 1901 Wasielewsky passed vaccine virus through forty-eight successive transplantations, the thirty-sixth giving successful vaccination against smallpox, and in each case these inclusions were present and in approximately the same number, showing that reproduction had taken place. Councilman, Magrath, and Brinckerhoff found that in variola the cell inclusions are present both in the cell bodies and in the nuclei, while in vaccina they are present only in the cell bodies. They concluded that the intranuclear position indicated a phase responsible for the greater malignancy of smallpox. Calkins ("Protozoology," 1909, p. 308) is inclined to think that the Guarnieri bodies are rhizopods and describes the probable life history of the organism. He interprets the finer granules as vegetative spores of merozoites; the body ruptures and the spores are liberated to be carried by the blood to new regions of the skin where the cycle is repeated. In vaccina this vegetative cycle appears to be the only phase of the life history. In variola, however, the nucleus finally becomes infected and the parasites develop in a more definite manner with the formation of chromidial fragments.

Recently J. Siegel (*Centralblatt für Bakteriologie*, etc., I Abt. Orig. Bd. 59, Heft 4, 406) has succeeded in obtaining this organism in pure culture. He recognized in 1904, in the blood and internal organs of calves and rabbits which had been vaccinated, minute bodies which he considered identical with the *Cytoryctes guarnieri* of the rabbit's cornea. In 1910 he made cultures from the tissues of a calf which had suered very severely from vaccina. Several tues were made of equal parts blood and bouillon, and small pieces of spleen were dropped into bouillon. These were all left at room temperature (not above 25° C.) in a dark place for ten days, when transfers were made to slant agar tubes. After eight days he found in each tube greater or smaller numbers of small transparent colonies, consisting of sharply circumscribed round and oval disks with granular contents. It is well known that the virulence of calf lymph quickly decreases and disappears when it is kept at a temperature of over 30° C., so one is not surprised to find here that the first culture at least grows best at 25° C., and indeed at incubator temperature generally refuses to grow at all. If the organism once becomes acclimated to agar media, it produces slimy, yellowish-white, raised colonies. The color varies, usually becoming brighter as the colony grows older. The virulence lessens with age, so that from old colonies it is necessary to transfer a much greater quantity of material in order to inoculate a fresh tube.

The morphology of Siegel's organism is very interesting. In the smear or in the spleen preparation, it appears as a delicate coccus about 0.2-0.3μ in diameter and is very difficult to find, being easily mistaken for a granule of precipitated stain. When grown upon agar, especially if the medium is fresh and rich in water of condensation, the forms are much larger and tend to acquire a mucous capsule and to clump together. They stain easily with Loeffler's methylene blue. The small forms are Gram negative, while the larger encapsulated ones are Gram positive. From their morphology they may be included with the diplococci or the staphylococci, but they have nothing in common with the pyogenic cocci, they never produce pus or cloud bouillon, and the growth is best at a low temperature. On account of these peculiarities he thinks it is perhaps better to include them in a separate group under the name *Cytoryctes cocci*.

Siegel inoculated one man in four places on the arm with the greater part of an agar culture. At the point of inoculation there appeared a slight inflammatory swelling of the skin, but no typical vesicles or papules. In five days everything had apparently disappeared. After twelve days, however, constitutional symptoms developed with fever and severe headache. Also there appeared solitary papules on various parts of the body, some being surrounded by an inflammatory areola. The whole attack lasted several weeks and gave the impression of a light attack of variola. He then turned to rabbits. Wasielewsky had convincingly demonstrated the specificity of the *Cytoryctes guarnieri* in the inoculated rabbit's cornea. Siegel using his cultures was able to get fairly constant, though not absolutely conclusive, results. Biological proof seems difficult, as all agglutination and complement fixation tests have so far yielded unsatisfactory results. He concludes that it is possible to find in the blood and spleen of vaccinated calves small bodies which, under the name of *Cytoryctes guarnieri*, are described as occurring in the rabbit's cornea when infected with vaccine lymph, and he has with some success demonstrated that the cornea shows the same changes when inoculated with a pure culture of this organism as those which develop in the presence of the *Cytoryctes guarnieri*.

Of course the demonstration cannot be regarded as final, but at the present time the burden of proof would seem to rest upon the opponents of this contention.

MILK DEPOTS AS A FACTOR IN THE REDUCTION OF INFANT MORTALITY.

Owing to the various articles of late appearing in the press and magazines of the country it is of interest to note the review written by Dr. Kerr of the United States Public Health and Marine Hospital Service, and published in Public Health Report for August 18 under the caption "Data Regarding Operations of Infant Milk Depots in the United States in 1910." Forty-three institutions located in thirty cities furnished details as to their operations, maintenance, method of instruction, number of children fed, average age, form of milk used, and mortality rate. Owing to the lack of uniformity existing in the various institutions it is difficult to make any accurate comparison of the data furnished. The general object seemed to be the protection of life and the effort to attain this end fell under two main headings; first, the teaching of the hygienic needs of the infant; second, the relief of distress due to poverty.

Twenty-nine of these depots were maintained by private funds only. Three cities supported stations out of the public funds. Forty-one gave instructions by means of literature or by the personal teaching of physicians and nurses in matters pertaining to infant hygiene. Some institutions furnished milk free, others sold it at varying prices. A number furnished milk to expectant mothers or as an aid to nursing women, thus indirectly enhancing the infant welfare. Several institutions distributed milk to sick children only, while at two none of the applicants were sick. In the vast majority, however, the applicants were already ill, which seems to show that it is for the sick infants that the milk depots are at present most needed. The proportion of children improving or remaining well while taking the milk indicated decidedly good results, although this statement has to be made with some reservation as the data furnished were somewhat indefinite and the most accurate conclusions could be drawn only from the statistics of such depots as furnished milk during the entire year. As a number were in operation only during the summer months, the value of the observations was necessarily less in such cases. The average age of the applicants was under one year, with extremes of two days to twelve years. As a rule, milk was prepared from standard formulæ, though in some cases private physicians were allowed to prescribe for their individual patients to meet the particular needs in question. About 15 depots furnished heated milk, 17 raw milk only, and 5 both heated and raw. The temperature used in pasteurization varied in different plants from 140° F. to 170° F., and the time from 10 to 40 minutes, or an average of 20 minutes minimum exposure. In some institutions the milk was heated winter and summer, in others in summer only. All reported using the best milk obtainable and in some cases certified milk was used.

When one takes into consideration that the majority of these infants were sick and came from poor surroundings the general impression is gained that the average mortality rate of those fed on dispensary milk for one month or over was relatively small. This, however, is only a general impression, for in order to have accurate mortality rates we must have accurate birth dates, and as in many cities the registration of births is woefully incomplete it is impossible to determine the infant mortality with accuracy. As the registration of vital statistics is universally conceded to be the true foundation upon which the science of preventive medicine must rest, the report of Dr. Kerr only emphasizes anew the truth that progress along these lines is greatly impeded by the lack of uniformity, not only in the recording of births and the causes of deaths, but likewise in the widely different methods and aims of our various institutions for research. The hopeless confusion existing might be easily remedied by the creation of a federal department with a central medical head whose aim it should be not only to safeguard the public health but also to establish a system of uniformity in the methods of observation and thus reduce the immense available data to some orderly system which would permit of accurate scientific interpretation at the hands of the trained statistician.

AVIATION SICKNESS.

It follows naturally that after the adoption of flying on a wide scale morbid manifestations peculiar to the change of meteorological conditions to which those who travel through the air at varying altitudes and at great speed are subjected should be the subjects of medical study. In the first instance, in the case of those who take part in the very hazardous occupation or excitement of guiding and managing an aeroplane there must be great stress placed upon the nervous system, more probably greater than in any of the strenuous pursuits, not even excepting automobile racing, to which the present generation is so prone, but this aspect of the matter is foreign to the present discussion. In the *Medical Press and Circular* of August 23 reference is made to a communication by Crouchet and Moulinier to the French Académie des Sciences as a result of their observations on several aviators who took part in the Bordeaux contest.

According to these observers there are two kinds of troubles from which aviators suffer. The first is due to the altitude attained, the second to the physical effort put forth. The special factors of the altitude question are difference in pressure and difference in the chemical composition of the air. Of course, the difference in pressure is very considerable and the difference in chemical composition of the air is also quite marked at great heights, and, further, there is the difference in the temperature. There are, however, in the case of aviators two very special adverse factors to which Crouchet and Moulinier attach great importance, viz., the rapidity of the ascension and still more the rapidity of the descent. The speed of the ascent is ofttimes very

great, but the rapidity of the descent is fantastic and almost gruesome. The biplane and monoplane differ somewhat with regard to the speed of ascension, but the rate of descent is about the same for both.

So far as the ascent is concerned respiration becomes shorter when a height of 1,500 meters has been reached and tachycardia increases. Nausea is not a symptom, but an undefinable kind of malaise is present. As for the auditive phenomena, a slight deafness is experienced at the height of 1,000 meters; at a somewhat greater height noises in the ears commence. Vision remains intact. The following are some of the other sensations which have been remarked: headache, sensation of cold above 2,000 meters (6,500 ft.), an intense desire to urinate, while the movements of the body are brusque and jerky. The morbid phenomena which distinguish the descent are chiefly these: a sensation of anguish like that which accompanies the sudden descent of an elevator, violent palpitations, greatly increased noises in the ears, and a more imperative desire to micturate. The most characteristic of all the troubles are a burning sensation of the face and disagreeable smarting of the eyes with an almost irresistible desire to sleep. On landing the aviator is not free from the above sensations for a considerable time. Respiration quickly returns to normal, but arterial hypertension is still well marked and persists for quite a long period after the flight is finished.

As may be imagined explanations of these phenomena differ as much as the phenomena themselves differ. Evident rôles may be attributed to variations of temperature, the cold, speed, and so forth. With regard to the troubles of circulation the authors are of the opinion that the cause may be sought in the rapidity with which the human organism passes through the different conditions of atmospheric pressure, though it is not reasonable to exclude altogether the nervous element.

Dr. Wiley Upheld.

After a very thorough investigation of the charges against Dr. Harvey W. Wiley, Chief of the Bureau of Chemistry, in connection with the employment of Dr. H. H. Rusby, President Taft, in a letter to Secretary Wilson of the Department of Agriculture, exonerates Dr. Wiley and refuses to administer the "condign punishment" recommeded by the Personnel Board and the Attorney-General President Taft finds that the recommendations of the board were based upon insufficient evidence and that the appointment of the Remsen Board was sufficient precedent to warrant the employment of Dr. Rusby at an annual salary, although only a portion of his time was devoted to the work of the bureau. Dr. Rusby is also declared guiltless of any attempt to evade the law in accepting compensation at the rate of $20 a day; but Drs. Kebler and Bigelow are to he reprimanded for "overzeal" in squaring Dr. Rusby's desire for adequate compensation with the contract which the Secretary of Agriculture and Dr. Wiley were willing to make with him. The President evidentally does not regard the "overzeal" as a very heinous offense, and the "reprimand" will doubtless be a mere formality. The boomerang which Dr. Wiley's opponents threw is still flying back, and may hit somebody even yet. And as for Dr. Wiley himself, if he will only acknowledge his error in the carrying out of the benzoate tests everybody will love him and peace will be his portion.

Mushroom Poisoning.

Every summer and autumn many deaths occur from the eating of poisonous mushrooms, but this season appears to be especially notable in the number of cases of poisoning by these fungi. The heavy rains coming after a dry summer caused the growth of mushrooms in profusion and men and women gathered and ate them with reckless disregard of the consequences. The majority of the sufferers are Italians who have more excuse for this fatal error than the native hunter. Most of the poisonous agarics in this neighborhood belong to the genus *Amanita*. Some of the species of this genus are edible, it is true, but the majority are poisonous and the distinction between the good and the bad is so subtle, except for an expert, that the safe rule is never to pluck any form of *Amanita*. In Italy, however, there is an edible species, *Amanita cæsarea*, or Cæsar's mushroom, which has supplied Italian peasants and Roman epicures alike with food for many centuries. It closely resembles the fly agaric, *Amanita muscaria*, and the newly arrived Italian roaming the fields naturally seizes upon the familiar object and brings it home for himself and family to feast upon. The edible mushroom is a delicacy, but its food value is greatly exaggerated, for it contains hardly as much nourishment, weight for weight, as a turnip. Those who like its taste and who can recognize it without the possibility of error may pluck it and enjoy it, but one who is not sure will do well to leave every form of mushroom severely alone. The risk is too great, for there is often poison in this cup.

Scleroma.

The affection once known as rhinoscleroma and classed among dermatoses has now by common consent become known simply as scleroma, while its localization as far down as the trachea has been responsible for placing it rather in the province of the laryngologist. The subject was discussed at the recent meeting of the German Laryngological Society (*Münchener medizinische Wochenschrift*, August 1), and some points of importance, if not of novelty, were brought out. The affection was formerly believed to be confined to two races not ethnically related, viz., the Jews and the Slavs, this resulting evidently purely from propinquity. Recently it has been encountered in Bohemia and thus seems to be traveling westward. Its cause is commonly accepted as Frisch's bacillus, which has been found even in the enlarged lymphnodes proper to the affected localities. The entire pathogenesis, including the mode of transmission, remains obscure. Ehrlich's 606 destroys the bacillus *in vitro*, but not *in vivo*. Many cases of improvement and even of cure have been accredited to the action of the *x*-rays. It behooves the health officers along the frontier of the area of prevalence of the disease to be on the watch for cases in the hope of preventing its spread.

News of the Week.

Health of the Canal Zone.—For the month of June, 1911, a total of fifty-one deaths from all causes among employees was reported. This gives an annual rate of 12.61 per thousand, which is somewhat larger than the rate for the same month of the previous three years. The following table gives the death rate among employees during June of previous years:

1904	5.02
1905	16.44
1906	41.55
1907	27.53
1908	12.35
1909	9.34
1910	10.66

Including both employees and civil population the death rate in the cities of Panama and Colon, and in the Canal Zone for the month of June of each year is as follows:

1905	50.57
1906	51.89
1907	33.45
1908	29.17
1909	16.42
1910	20.38
1911	25.33

Among employees the deaths from the principal diseases during the month were as follows: Nephritis, 6; hemoglobinuric fever, 2; malarial fever, 7; organic heart disease, 3; lobar pneumonia, 9; tuberculosis, 3; typhoid fever, 2. Thirteen deaths were due to external violence. The epidemic of measles noted in the reports for May and April had almost entirely subsided, but a slight epidemic of diphtheria prevailed, twenty-nine cases of mild type having been reported. All had yielded readily to antitoxin treatment. No cases of yellow fever, smallpox, or plague originated on or were brought to the isthmus during the month. The health officer of Colon reported a large increase in the number of deaths, 62 per cent. of the total number being of children under five years of age. The work of sanitation throughout the district has been carried on as usual.

Christian Science Deaths.—Attended only by Christian Science "healers," E. H. Carlmark of West Orange, N. J., died of typhoid fever recently. Two physicians were allowed to see the patient and diagnose the case, but both the sick man and his family refused to allow medical attendance.

A coroner's jury investigated the death of Arthur W. Eager of New York, and after listening to the testimony of the Christian Science "healer" who had attended him for three years returned a verdict that death was due to a complication of disorders caused by a lack of medical treatment.

Hospital in Danger.—The Fire Marshal of the State of New York reports that the inmates of the Long Island State Hospital at Kings Park are in danger through lack of proper precautions against fire. The report recommends the destruction of one building now used as a dormitory by 300 patients, which was not originally intended for the purpose and which is inadequately protected. It also calls attention to the lack of proper appliances for utilizing the water supply in case of fire.

Reports of Deaths in Illinois.—The State Legislature has recently amended the law covering the reports of births and deaths, making it the duty of the official giving burial permits or receiving reports of deaths to deliver to the State Board of Health on or before the tenth day of the month all certificates of death presented to him during the preceding month, and providing for the payment to such official of a fee of ten cents for each death so reported. These fees are to be a charge on the county in which they accrue.

Health of Houston, Tex.—During the year ending July 31, 1911, there were 1,400 deaths reported to the Health Department of Houston, a decrease of 102 from the total for the previous year, the death rate per thousand being only 13.7. During the same period the births numbered 1,821, exceeding the deaths by 421.

Typhoid Fever Outbreak.—A small epidemic of typhoid fever among the inmates of the village for epileptics at Skillman, N. J., has been reported. The source of the infection has not been determined.

School Children's Teeth.—The first report of the Dental Hygiene Council, appointed by the Board of Education of the City of New York, shows that about 60 per cent. of the children so far examined have defective teeth. The establishment of a free dental clinic and of a regular system for the inspection of pupils' teeth is being agitated as a result of the investigation.

Vaccinated Against Typhoid.—About 5,000 sailors from the ships in Admiral Osterhaus' fleet lying in Hampton Roads have received the vaccination treatment as a preventive of typhoid fever.

New University Hospital.—The new Elliot Memorial Hospital of the University of Minnesota was dedicated with appropriate ceremonies on September 5, Dean F. F. Wesbrook of the College of Medicine and Surgery presiding. The hospital building is situated at the extreme end of the University campus on a high bluff overlooking the Mississippi, and was made possible through the gifts of the late Dr. Adolphus Elliot. Under the regulations only patients unable to pay will be admitted. For the last two years the hospital service has been maintained in temporary buildings, and during that period more than 1,000 patients from all over the State have been cared for, and over 500 operations have been performed. In connection with the dedication ceremonies the corner stone of the new Institute of Anatomy of the University was laid.

Health Department Bulletin.—Arrangements have been made for the publication of a somewhat larger edition of the Monthly Bulletin of the New York Department of Health, and it is hoped that it will eventually be possible to publish an edition sufficiently large to enable every physician to receive it regularly. The paper is now sent free at the request of any physician in the city. Applications should be sent to the Commissioner of Health, New York.

Fatalities in India.—The British Government has published a record of the contest for existence between man and beast in India. During 1910 23 elephants were killed, but they caused the deaths of 55 persons; 1,421 tigers were killed, and their victims numbered 853. Altogether of the total population of 300,000,000, the number of persons killed by wild beasts during the year was 2,400, but this does not include the deaths caused by snakes, which amounted to 22,478, while 91,104 snakes were destroyed, a ratio of about 1 to 4. This seems a heavy toll to pay to the beasts of the jungle at this late day.

Tuberculosis Sanatoria.—Four large fraternal

orders, two international labor unions, and one of the great insurance companies now maintain sanatoria for the treatment of tuberculosis among their members. The sanatorium of the Royal League is at Black Mountain, that of the Modern Woodmen of America at Colorado Springs, and that of the Workmen's Council at Liberty, N. Y., while the Independent Order of Foresters have one sanatorium at Rainbow Lake, N. Y., and will soon open another at San Fernand, Cal. The Typographical Union and the International Pressmen's Union conduct institutions at Colorado Springs and Rogersville, Tenn., while the Metropolitan Life Insurance Company has a new sanatorium at Mt. McGregor, N. Y. One of the larger life insurance companies has recently established a "Conservation Department" in which the prevention of tuberculosis will be given special attention, and other insurance companies are considering similar action.

Disease in Haiti.—The second medical commission appointed by the Haitian Government, consisting of Drs. James Donnelly, Doucet, Boyer, and Delancourt, has gone to Ouanaminth, where the sanitary conditions have been a matter of much concern. A thorough investigation will be conducted.

The Cholera.—The cholera situation in Turkey, which has been very serious, is rendered worse by the attacks made upon the sanitary officers who are attempting to enforce the regulations in regard to the control of the disease. In Monastir a mob, led by a priest, drove the health commissioner from his office and compelled the reopening of the contaminated water supply and the withdrawal of the regulation against the sale of fruit. In Constantinople an average of 25 deaths and many new cases of the disease are reported daily. There has also been an outbreak of the disease at Mecca, and this is causing great alarm because of the approaching pilgrimages. In Italy, for the week ending September 3, there were 1,468 new cases and 648 deaths. The totals from June 26 to September 3 were 10,634 cases and 4,086 deaths.

Euthanasia Again.—Two members of a Shaker settlement at Kissimee, Fla., were arrested recently on the charge of having caused the death, by the administration of chloroform, of a sister member of the colony who was ill with tuberculosis. The accused persons admit the truth of the charge, and in explanation of their action state that the patient had been ill for a long time and had begged to have her sufferings ended, and that in administering the chloroform and thus making death easy they simply followed the guidance which came to them in answer to prayer. The two were admitted to bail, the judge having refused to consider a charge of murder in the first degree. Public opinion in the neighborhood of the settlement is divided, but ample money and legal talent have been secured for the defence.

The Quarantine Investigation.—The taking of direct testimony by Commissioner Bulger, who has been conducting an investigation of the New York Quarantine Station, was recently completed, and a brief analyzing the charges against Dr. Doty and reviewing the testimony has been submitted by his counsel, Mr. George Gordon Battle. Mr. Charles Dushkind, representing the Jewish newspaper which has been attacking Dr. Doty, has also turned in his brief, so that the commissioner now has the entire case before him.

Inebriety Board.—The first meeting of the new Inebriety Board for the reclamation of the habitual drunkard was held recently in the aldermanic chamber at the City Hall, New York. It was decided to open headquarters in the old police building at 300 Mulberry street on October 1, and after that date the police will be called upon to furnish the board with data as to all arrests for intoxication. The board expects shortly to acquire a site within a short distance of the city on which hospital buildings will be erected at a cost of about half a million dollars.

Bequests to Charities.—By the will of the late Thomas D. Crimmins of New York, St. Vincent's Hospital and Seton Hospital receive each $2,000, and St. Joseph's Hospital receives $500.

The Presbyterian Hospital of New York receives $1,000 under the will of the late Samuel Hall of Rye, N. Y.

A bequest of $500 is left to the Lynn Hospital in the will of the late David F. Adams of Lynn, Mass.

Columbia University, New York, receives one-half of the estate of the late Mrs. George Roe Lockwood, subject to the life interest of her husband, the income to be used toward assisting deserving students in the third and fourth years at the College of Physicians and Surgeons.

Reorganization of Medical College.—The University Medical College of Kansas City, Mo., has recently been reorganized and has received the endorsement of the American Association of Medical Colleges. The college offers only the work of the junior and senior years of the ordinary medical course, students being admitted on the completion of the first two years in other colleges. Special post-graduate work in bacteriology and pathology will also be offered.

Course in Internal Medicine.—During the coming season Dr. William E. Hughes and Dr. Robert N. Willson will as usual conduct six post-graduate courses in internal medicine at the Philadelphia General Hospital, each course to be of six weeks' duration. Both men and women physicians will be admitted to the lectures, which will take the form of informal clinical conferences on the cases in the wards of the hospital. No fees will be charged.

Death of Centenarian.—Mrs. Anne Murphy of San Diego, Cal., died at the Old Folks' Home in that city, on September 12, at the age of 110 years.

Harvey Society.—The Harvey Society announces that the following distinguished lecturers have been secured for the coming season: Prof. W. B. Cannon of the Harvard University Medical School; Prof. R. H. Chittenden of Yale University; Dr. Simon Flexner of the Rockefeller Institute for Medical Research; Prof. H. S. Jennings of Johns Hopkins University; Prof. Albrecht Kossel of the University of Heidelberg; Prof. H. F. Osborn of Columbia University; Dr., J. J. Putnam of Harvard University; Prof. T. W. Richards of Harvard University; Prof. W. T. Sedgwick of the Massachusetts Institute of Technology; Dr. W. S. Thayer of Johns Hopkins University, and Prof. Verworn of the University of Bonn. During the month of October the following lectures will be delivered: October 7, Local Specific Therapy of Infections, by Dr. Simon Flexner; October 14, The Chemical Structure of the Cell, by Prof. Albrecht Kossel; October 28, Anesthesia, by Prof. Verworn.

Dr. S. J. Meltzer of the Rockefeller Institute for Medical Research has recently been elected a member of the German Academy of Natural Science, Berlin. This is a very old institution, having

been established in 1652, and but four Americans have been honored by election to it.

Civil Service Examination.—The New York State Civil Service Commission will hold examinations on October 14, 1911, for the purpose of filling the following positions: Chemist, Department of Agriculture, at a salary of $900 to $1,500; pharmacist, at a salary of $540 to $900 and maintenance; trained nurse, at a salary of $420 to $900 and maintenance. Application blanks can be obtained from the State Civil Service Commission, Albany, N. Y.

Course in Clinical Physiology.—The Department of Physiology of the College of Physicians and Surgeons, Columbia University, New York, offers a new post-graduate course entitled Clinical Physiology, which will comprise a series of selected topics on the application of physiological principles to the problems of clinical medicine. These will include the newer methods of physiological registration, the viscosity of the blood in health and disease, edema, the measurement of blood-pressure in man, the electrocardiographic method and its application in diagnosis, the mechanism of the heart beat, etc. The course will consist of fifteen weekly exercises, and will be given by Drs. R. Burton-Opitz, F. H. Pike, Haven Emerson, and H. B. Williams of the Department of Physiology. It is open to doctors of medicine, and those who desire to take it are requested to communicate with Prof. Frederic S. Lee of the Department of Physiology, 437 West Fifty-ninth street, New York, before September 27.

A Young Swindler at Work.—Dr. George E. Davis of this city writes: "For the benefit of the other members of the profession I wish to make the following report of a swindle being worked in New York City. A boy of about fifteen years, rather stout, brown hair, purporting to be a messenger from Johnson & Johnson, calls at doctors' offices, out of hours, with a package of sand in collar boxes, wrapped in brown paper, marked with a pencil, "$3.00 Collect," or some such amount. In this instance the door-boy asked for the bill and was told it was inside of the package. The door-boy then paid the amount without opening the package and the fraud was not discovered until after the messenger had gone."

The Study of Tropical Medicine.—Tulane University, New Orleans, has established a Department of Tropical Medicine under the charge of Dr. Creighton Wellman, the first course to begin October 1.

Dr. Bull's Library for the Academy.—The children of the late Dr. Charles Stedman Bull have presented his entire medical library to the New York Academy of Medicine.

Cocaine Addiction Among Negroes. — The Grand Jury of Hinds County, Mississippi, has presented a report stating that "The use of cocaine is alarming, principally among the negroes, who in some sections of the county, when short of cash, have actually bartered their farm products for the drug. We trust good citizens will continue to assist the officers in rooting out this evil, which is demoralizing labor and filling the jails with criminals."

Dr. M. Howard Fussell has been elected professor of applied therapeutics in the medical department of the University of Pennsylvania.

American Electrotherapeutic Association.—At the twenty-first annual convention, held in Philadelphia on September 5 to 7, the following officers were elected for the ensuing year: *President*, Dr. William D. McFee, Haverhill, Mass.; *Vice-Presidents*, Dr. F. Howard Humphris, London, England, and Dr. George E. Pfahler, Philadelphia; *Treasurer*, Dr. Emil Heuel, New York; *Secretary*, Dr. J. Willard Travell, New York; *Registrar*, Dr. Frederick M. Law, New York.

Missouri Valley Medical Association.—The annual meeting of this society was held in Omaha, Neb., on September 7 and 8, when the following officers were elected for the ensuing year: *President*, Dr. J. M. Bell, St. Joseph, Mo.; *Vice-Presidents*, Dr. A. C. Stokes, Omaha, and Dr. S. Grover Burett, Kansas City, Mo.; *Secretary*, Dr. C. W. Fassett, St. Joseph; *Treasurer*, Dr. O. C. Gerhardt, St. Joseph.

Obituary Notes.—Dr. Maurice Dwight Clarke of Haverhill, Mass., a graduate of the Harvard University Medical School in 1882, a member of the Massachusetts State and Essex County Medical Societies, formerly president of the latter, and secretary and treasurer of the Haverhill Medical Society, president of the consulting board of the Danvers Insane Hospital, city physician of Haverhill from 1892 to 1897, and a member of the board of health from 1892 to 1909, died at his home of paralysis on September 8, aged 59 years.

Dr. Eugene A. Hultz of Perth Amboy, N. J., a graduate of Hahnemann Medical College, Philadelphia, in 1886, died at his home September 5.

Dr. John E. Lockridge of Nevada, Iowa, in practice in Indianapolis, Ind., until last April, a graduate of the Medical College of Virginia, Richmond, in 1863, died at his home last month.

Dr. Isaac Buckeridge of Beloit, Wis., a graduate of Hahnemann Medical College and Hospital of Chicago in 1883, died at his home after a prolonged illness August 30, aged 61.

Dr. Jacob Weber of Philadelphia, a graduate of the University of Pennsylvania, Department of Medicine, in 1858, died at Cape May, N. J., August 28, aged 86.

Dr. Starling Loving of Columbus, Ohio, a graduate of the Starling Medical College of Columbus in 1849, and the oldest alumnus of Bellevue Hospital, New York, and a member of the American Medical Association and of the Ohio State and Franklin County Medical Societies, died at his home on September 2 aged 82 years.

Dr. Frank E. Waxham of Denver, Col., a graduate of the Northwestern University Medical School, Chicago, in 1878; professor of laryngology and rhinology in the Colorado School of Medicine, Boulder; a member of the medical staff of St. Joseph's Hospital; laryngologist and rhinologist to the University Hospital, the National Jewish Hospital, the Children's Hospital, and the Central Free Dispensary, and consulting laryngologist to the Denver City and County Hospital; a member of the American Medical Association, the Colorado Medical Society, the Medical Society of the City and County of Denver, and the Denver Clinical and Pathological Society, died at home of paralysis, on September 4, aged 59 years.

Dr. Isaac Buckeridge of Beloit, Wis., a graduate of the Hahnemann Medical College of Chicago in 1883, and a member of the Wisconsin State and Rock County Medical Societies, died at his home on August 30, aged 61 years.

Dr. Alfred W. Mitchell of Humansville, Mo., a graduate of the Medical Department of Washington University, St. Louis, in 1879, died suddenly at his home, on September 4, aged 55 years.

Obituary.

THOMAS DWIGHT, M.D., LL.D.

BOSTON, MASS.

Dr. Thomas Dwight, Parkman professor of anatomy in the Harvard University Medical School since 1883, died at his summer home in Nahant, after a long illness, on September 8, aged 68 years. Dr. Dwight was a graduate of Harvard University, receiving the degree of A.B. in 1856, and of M.D. in 1867. In 1872 he became instructor in compartive anatomy in the Harvard Medical School, and in 1874 was made instructor in histology, and in 1880 instructor in topographical anatomy. In 1883 he was apointed professor of anatomy, succeeding Dr. Oliver Wendell Holmes in that chair. From 1872 to 1876 he was professor of anatomy in the Medical School of Maine, Bowdoin College. Dr. Dwight was a member of the American Medical Association, the Association of American Anatomists, and the Massachusetts State and Suffolk County Medical Societies, and an honorary member of the Anatomical Society of Great Britain and Ireland. From 1873 to 1878 he was editor of the *Boston Medical and Surgical Journal*, and in 1884 delivered the Lowell Institute Lectures. He was a convert to the Catholic Church, and only recently published an interesting book entitled "Thoughts of a Catholic Anatomist," in which he discusses a number of topics relating both to biology and to catholicism. In 1889 he received the honorary degree of LL.D. from Georgetown University in recognition of his contributions to medical science.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

SCIENCE CONGRESS—THE BREAD CONTROVERSY—THE TWO SANITARY INSTITUTIONS—SMALLPOX—MALINGERING—OBITUARY.

London, September 1, 1911.

We are now in the middle of our chief scientific congress—that of the British Association for the Advancement of Science, which is holding its eighty-first annual meeting. It was in 1830 that Sir David Brewster proposed the formation of such a society, and the next year the first meeting was held at York, when 325 members were enrolled. It grew rapidly in favor, and at the Manchester meeting (1887) the number rose to 3,838. Since then there has been a sad decline, although at the Liverpool meeting (1896) there was a rise again to 3,181. Last year the attendance had again fallen to 1,449. This year the meeting is being held at Portsmouth, and it was hoped that so interesting a town, with its numerous attractions of an almost unique character, and the nearness of other favorite places would bring a return of prosperity. So far, however, there seems reason to fear it will not be so—at any rate in respect to numbers, for up to this morning only 1,200 had put in an appearance. Something seems necessary to increase the popularity of the congress, but the solid work has not fallen off. I turn, then, to the proceedings, which were formally opened in the Town Hall at Portsmouth on Wednesday evening. Sir William Ramsay succeeds Professor Bowney as president, and delivered his address, which was chiefly devoted to an exposition of ancient and modern views regarding the elements. He referred to the fact shown by radioactivity of ome twenty-six unsuspected elements and to the amazing amount of energy stored up in radium. An illustration of the last point elicited no little applause. If, he told his audience, they could utilize the energy of a ton of radium it would suffice to propel a ship of 15,000 tons, with engines of 15,000 horsepower, at the rate of fifteen knots an hour for thirty years. The illustration was popular, but there is great virtue in an "if," and to this particular if he had to say that the production of radium would not surpass half an ounce a year. As coal is our principal source of energy, Sir William pointed out that the amount stored up in British coal fields, which is somewhere about 100,000,000,000 tons, if the rate at which it has been increasingly exploited for the last forty years continue, will be completely exhausted in 175 years. He recommended less wastefulness of the national wealth. Yesterday the sections, of which there are eleven, began their work, each with an address by its president.

For some months past there has been a good deal of loose talk about bread as the staff of life and the deceptions practised in its preparation. The newspapers took up an old cry about whole meal bread, and then the bakers offered what they called a "standard loaf." It was freely exploited and boomed by those interested, as well as a number of invalids and dietetic self-made authorities. But either the brown color or the sticky consistence did not please the public taste and the white loaf still retains its preeminence. Nevertheless the advocates of whole meal bread continue their efforts to extend its use, and some of them are rather extreme in their statements. As an example, Miss Yates, honorable secretary of a Bread and Food Reform League, read a paper on the "Standardization of Bread" at the recent congress of the Royal Institute of Public Health, in which she said boys fed on the standard bread gained more in height and weight than those who consumed only white bread. Then she talked of millions of workers making white bread the basis of their diet, not realizing that it was starvation food and tended to produce tuberculosis, physical degeneration, the drink crave, nervous diseases, and appendicitis! Is it not amazing that so many civilized people are yet alive? A resolution was adopted in the interests of poor children to encourage a demand for the supply of bread containing the maximum nutriment of wheat with a small amount of the indigestible woody fiber.

You may think in this case that the Institute's discussion was scarcely needed, but it has been supported by various authorities and some medical ones have expressed themselves almost as extravagantly. On the other hand, the Local Government Board has issued a valuable report on the subject, which may serve as a corrective to the many rash assertions that have been freely circulated. This report is prepared by Dr. J. M. Tamill and gives an account of the varieties of wheaten flour and indicates the chemical and physiological evidence as to their dietetic values. Only genuine flours are considered, and Dr. Hamill does not attach great importance to the differences in nutritive value between breads made from the several kinds of flour milled from good samples of grain. The notion that ordinary high grade and white "patent" flour is devoid to a great extent of protein, whereas it abounds in "entire" wheat flour, he pronounces to

be erroneous. The differences are not relatively of great magnitude and may well be neutralized by imperfect absorption. There are wider differences in protein content and nutritive value between flours from different wheats than between patent and entire flour from the same wheat. A "patent" flour from one variety of wheat may contain more protein and furnish more energy than an "entire" or "whole meal" flour from another variety of wheat. It is asserted that whole meal bread is not so likely to aid the production of dental caries by fermentative changes, but no evidence has been put forward which can be considered conclusive on this point.

On several occasions lately I have had to mention the Royal Institute and the Royal Sanitary Institute, and as both have now concluded their annual meetings, having held them simultaneously at Belfast, you may like to have a note as to their respective constitutions. The Royal Institute of Public Health was founded in 1886 in order to push forward the registration of diplomas in public health and compel the provision of such diplomas by medical officers of health. There are now about 2,000 members who may avail themselves of the chemical and bacteriological laboratories and undertake researches; there is also a literary and lecture room. The institute trains for health diplomas as well as for research, and is recognized by the university.

The Royal Sanitary Institute is somewhat older, was founded in 1876, hold meetings at which papers are read and discussed and lectures and demonstrations given on sanitary subjects. Examinations are also held and certificates given. The Parkes Museum is maintaied by this institute, open to teachers and students for demonstrations, etc. The library is rich in sanitary publications. You will see that these two Royal Institutes, though differing somewhat in their work, overlap a good deal and it looks as if they might very well amalgamate. At any rate the holding of two annual meetings together in one city, discussing sanitary questions, is rather a trial and militates greatly against success.

A report respecting the late outbreak of smallpox has been supplied by the Asylums Board. The first case occurred in a poor-law infirmary and six patients were infected. In all 70 cases were received, 33 from the same district as the first. There were 11 deaths, a mortality of 15.71 per cent. Of the total number 46 were vaccinated, of whom one died. Twenty-two were not vaccinated, and of these nine died. Of three said to have been revaccinated before infection all recovered. The point of interest and importance about the outbreak is that the majority of cases were the result of the admission of one unrecognized case into a large institution. This suggests the advisability of revaccination of all persons employed in such institutions. At the Asylums Board's hospitals revaccination is compulsory, but not usually in Poor Law Infirmaries. The consequent danger is exhibited in this outbreak, for not only 21 of the poor patients in the infirmary, but seven members of the staff contracted the disease.

The danger of malingering under the insurance scheme has been discussed in various meetings. Dr. R. A. Lyster, medical officer of health for Hampshire, from his experience has reported that the only way to prevent it is to arrange for all cases on the sick list for a certain period—say a month—to be examined by independent medical referees. Some kind of unification of medical services to the public, he thinks, ought to be introduced. By linking up this new medical work with the existing health services it would be possible to build up a national scheme in which all medical service could be included. The new committees will have similar duties and responsibilities to those of county councils and enormously increase the present overlapping, confusion, and inefficiency which result from the multiplicity of agencies dealing with the sick poor. Unification of the services would also prevent friction and disputes which otherwise are sure to arise between new and established authorities.

Mr. Adam Rolland Rainy, M. P., who died suddenly on August 26, was a member of the medical profession and practised in London as an ophthalmic surgeon from 1887 to 1900, when he retired to contest a parliamentary seat. He failed on that occasion, but was successful in 1906, and has since been in the House. He was a son of the eminent Presbyterian leader, Principal Rainy, and born in 1862. He was educated at Edinburgh University and took M.B. and C.M. in 1886. He also attended some time in the Berlin and Vienna Universities. He had traveled a good deal, visited Australia, New Zealand (1891), Spain, and Algiers (1899 and 1903), the West Indies (1896). He was a member of the Ophthalmological and other medical societies, and had been president of the Edinburgh Speculative Society and the University Diagnostical Society. His death is a loss to the small band of doctors in Parliament.

Surgeon-Major John Ince, M.D., late of the Indian Medical Service, has died at the age of 81. He took his M.R.C.S. in 1854 and the next year the M.D. St. Andrews. He served as medical officer in Kashmir and civil surgeon at Murree, Rawal, and Pindi. He was a member of various societies, contributing valuable papers to them as well as to the journals. He was author of the Murree Handbook, the Kashmir Handbook, and official reports on cholera in Peshawur district and similar investigations.

David K. Coutts, M.B., F.R.C.S., assistant surgeon to the Norfolk and Norwich Hospitals, died on August 21 with tragic suddenness. Only five minutes after talking, apparently in good health, he was seized with unconsciousness and died in a few minutes at the age of 30. He had only been elected to the hospital staff some three months.

Geo. E. Jeaffreson, J.P., died in his 77th year on August 17 at Framlingham, where he had practised for many years and continued to reside after retirement and to help forward every effort for the benefit of the community.

Progress of Medical Science.

Boston Medical and Surgical Journal.

September 7, 1911.

Suits for Alleged Malpractice. G. W. Gay.
Some Comments upon the Probable Direction of Future Progress in Treatment of Chronic Joint Diseases. H. W. Marshall.
Humidity and Health. P. W. Goldsbury.
A Case of Pellagra. C. H. Dean.

Suits for Alleged Malpractice.—G. W. Gay quotes a court decision which states that "the medical practitioner is necessarily surrounded by doubt and uncertainties and unavoidably exposed to errors and mistakes, which may well furnish a satisfactory explanation of unfavorable results." Another element that is frequently suspected,

but unfortunately difficult to establish, is the contributory negligence on the part of the patient. Malpractice suits are brought from various motives, as, for example, to extort money from the defendant, to escape the payment of his bill, to avenge the disappointment at the termination of the case, to deliberately injure the reputation of the defendant out of spite, and to attract the notice and sympathy of friends and neighbors. A very important factor in many of these cases is the perniciously active attorney. Suits brought for the purpose of evading payment of the physician's bill may generally be successfully met by prompt legal action for the collection of the same. As long as the patient has his senses he has the right to refuse any and all methods of treatment of whatever nature. On the other hand, should an operation be performed in accordance with the dictates of common humanity, but contrary to the patient's consent and orders, the operator might be called upon to defend his action in court. In cases in which the patient is unconscious, or unable from any cause to decide these matters for himself, when coming under the care of a physician, the latter would be justified in performing any operation demanded by the emergency provided no one having authority should be present and refuse consent thereto. The physician should, however, protect himself by a consultation, if possible, and it might be well to explain the conditions and the reasons for the proposed operation to the bystanders. The entire transaction, together with the names of those present, should be a matter of record.

Treatment of Chronic Joint Diseases.—H. W. Marshall presents reasons and data to show how greater accuracy in diagnosis; greater skill in applying remedies accurately according to physiological needs of the tissues; discoveries of new methods of treatment through development of many medical researches; improvements in surgical knowledge and skill; and more keen appreciation of the advantages of preventive measures will all favorably influence progress in treatment of chronic arthritis.

Humidity and Health.—P. W. Goldsbury comments on the injurious effects of the indoor dryness of the atmosphere in winter. The irritation of the lips and throat and the parched feeling of the skin are common manifestations of these effects. On the other hand, rheumatism is an ailment which is particularly susceptible to moisture, as are also certain throat conditions. For some people the change from a moister to a dryer air may prove stimulating and produce favorable results. Others, probably of a more nervous type, would be benefited by the opposite change. The problem of constructing buildings in such a way as to keep the interior up to a fair degree of humidity is a large one. So far engineers have made little practical progress toward its solution. Clothing and covering of the body interfere more or less with an equal shading of humidity and evaporation and circulation of the air directly over the skin. Advantage may be taken of this fact. If the skin is allowed to enjoy longer periods of freedom from clothing upon retiring or rising, or when it is being changed, the body will be bathed more equally by air of a like degree of humidity and should benefit from such baths. If one must live much indoors he may improve the temper of his rooms by various devices, such as keeping growing plants and setting about porous dishes, as flower pots, full of water. After all there is nothing for humidity like the out-of-doors.

Pellagra.—C. H. Dean reports a case of this condition that he has observed in the Northampton State Hospital.

New York Medical Journal.

September 9, 1911.

Dilatation of the Heart in the Acute Fevers. H. Brooks.
Arteriosclerosis, Cardiosclerosis, and Intestinal Putrefaction. L. F. Bishop.
Greek, Ancient and Modern, and the Language of Medicine. H. C. Muller.
Crotalin Treatment of Epilepsy. R. H. Spangler.
A Preliminary Note on the Influence of Position in Relation to the Occurrence of Mastoiditis and Its Complications. C. A. Adair-Dighton.
Treatment of Fractured Thigh by a New Method, Involving a Principle Which Pertains to the Treatment of Fractures in General. W. H. Taylor.
Tendencies toward Race Degeneracy. J. H. Kellogg.
Treatment of Pneumonia Based on the Elimination of Sodium Chloride. H. G. Hughes.
A Curious Case of Tuberculous Meningitis. M. Freiman.

Cardiac Dilatation in Acute Fevers.—H. Brooks states that cardiac failure is common in acute rheumatic fever, in lobar pneumonia, septicemia, scarlatina, influenza, and especially in diphtheria. It is notably frequent in two definite groups of cases, first, those characterized by high and persistent fever and, second, those in which toxemia is pronounced. The lesion concerned is primarily an albuminous or parenchymatous degeneration of the heart muscle fibers as a result of which the elasticity, resistance, and contractile power of the muscle become diminished. Rapidity of heart action, particularly if irregularities in tension or in frequency occur, is indicative of impending dilatation. Auscultatory percussion will demonstrate this condition. A falling blood-pressure may be present and is a sign of great diagnostic and serious prognostic value. The treatment is preventive and directed against the condition itself. The toxemia is best combated by elimination. Drugs should not be given to slow the heart in these cases. The icebag to the precordium is a favorite method of controlling overaction of the heart in the acute fevers. The author does not favor digitalis in the acute condition, though he does employ it in convalescence. Morphine quiets the pain and lessens nervous excitement and the tension on the general circulation. Strychnine, adrenalin, camphor, and bleeding are other resources in this condition. Attention must be paid to conserve the heart muscle during convalescence. The patient should rest in bed and his diet should not contain too much fluid.

Arteriosclerosis and Intestinal Putrefaction.—L. F. Bishop believes that the majority of cases of arteriosclerosis are due to intestinal putrefaction which acts indirectly upon the blood-vessels and nervous tissue.

Greek and the Language of Medicine.—H. C. Muller in commenting on the movement to improve the language of medicine states that this reform cannot be accomplished apart from that to improve the language of other sciences, notably chemistry, botany, and zoology. The medical vocabulary consists of many hybrid terms. Medicine is not an exact science, but is a practical art which has formed its onomatology in the course of many centuries. The author doubts whether a radical reform will be possible. Medicine is above all a practical art and the majority of medical men will refuse to use modern Greek terms or those of a remote antiquity if there exists already a word of general use which is clear to the men of science and to the public. The reform can only be a partial one and can succeed in abolishing a great many incorrect and hybrid terms and in improving the artificial medical language as much as possible. The question is one that can be decided only by an international committee.

Crotalin Treatment of Epilepsy.—R. H. Spangler reports his results in the treatment of 36 cases of epilepsy treated with hypodermic injections of rattlesnake venom. These are given in doses of 1/200 grain, in most cases at intervals of five to seven days. The venom treatment is indicated in the so-called idiopathic form of epilepsy. Under the crotalin treatment the character of the convulsions is modified, the interval between the attacks lengthened, and the mental and physical condition of the patient improved. It is important to use a solution of the venom of definite and uniform strength.

Mastoiditis in Relation to Bodily Posture.—C. A.

Adair-Dighton presents a theory which apparently accounts for the predominance of mastoiditis on the left side. Owing to the position of the heart it is found by the great majority of people to be easier and at the same time more comfortable to lie on the right side when retiring to sleep. If chronic suppurative middle ear disease is present the position would favor drainage of the right ear but not of the left. This theory suggests the following line of treatment: The ears should be cleansed before retiring for the night, not by irrigation but by means of cotton wool mops.

Treatment of Fractured Thigh.—W. H. Taylor describes an elaboration of a method introduced by him of treating fractures by means of screws, to each of which, close to its head, a cross piece has been welded; the screw points to be inserted in the bone, the parts external to the skin to be imbedded in a mass of plaster of Paris, into which are incorporated a number of steel girders laid from cross piece to cross piece, converting the outer portions of the screws, their attached cross pieces, and the connecting girders into one continuous bridgework. It was further suggested that, without making an open wound, these screws might be inserted through the skin and the fracture set and immobilized under the *x*-ray.

Race Degeneracy.—J. H. Kellogg believes that the preservation of the unfit, while humane and altruistic, is nevertheless a menace to the race. Indoor life, the wearing of an excess of clothing, a diet containing an overabundance of flesh, alcohol and other poisons, city life, and race suicide are among the degenerative influences.

Treatment of Pneumonia.—H. G. Hughes states that an analysis of the urine of a pneumonia patient shows almost constantly absence of sodium chloride. He has found that the administration of potassium nitrate in full doses causes the sodium chloride to reappear in the urine within a few hours and to continue present as long as the potassium nitrate is given. The effect upon the course of the pneumonia is remarkable. The temperature almost invariably begins to fall within a few hours and continues to drop until it reaches normal. The physical signs remain for a few days, and then resolution begins and goes on to recovery without crisis. The author interprets these results as the manifestation of the early and gradual disassociation of the constituents of the exudate caused by the salt-free diet and the "dragging out" from the exudate of the sodium chloride by the administration of potassium nitrate.

Tuberculous Meningitis.—M. Freiman reports a case of this condition secondary to spinal tuberculosis.

Journal of American Medical Association.

Endemic Malta (Mediterranean) Fever in Texas with the Isolation of the *Micrococcus Melitensis* from Two Patients. Second Paper. E. R. Gentry, T. L. Ferenbaugh.
The Control of Typhoid Fever. L. L. Lumsden, W. C. Rucker, and A. W. Freeman.
How to Collect Old Medical Books in Europe. Where to Go and What to Look For. F. H. Garrison and F. Neumann.
Salicylates in Rheumatism. A. Lambert.
Herpes Zoster in Connection with Kidney Lesions. M. Krotoszyner.

Clinical Physiology.—Y. Henderson believes that internists and surgeons, and especially the professors of medicine and surgery in the medical schools, should be more interested, better trained, and more widely read in physiology. It were better if they read less in the clinical and more in the scientific journals; better if they talked and practised less, and investigated a great deal more. Physiologists must assume the duty of teaching not only normal but also abnormal physiology. Both should be taught in the second year of the medical course. In the future students who are being trained to be physiologists, whether in the field of physical and nervous or of chemical physiology, ought to have the medical degree.

Spinal Fractures.—By A. F. Jonas. See MEDICAL RECORD, July 8, 1911, page 100.

Mistletoe.—A. C. Crawford concludes from his pharmacological investigations that at present the data are not sufficient to identify the active pressor principles of our Southern mistletoes.

Tuberculous Tonsils.—E. C. Sewall finds that after removal of enlarged tonsils swollen tuberculous glands often diminish in size, though not always permanently. Certain tuberculous glands are not associated with tuberculous tonsils. The author believes that tubercle bacilli can travel to the glands without damage to the tonsil, and this accounts for the following facts (also for the higher percentage of tuberculous glands): Glands once tuberculous, associated with tuberculous tonsils or not, may enlarge even after the tonsils have been removed. One finds tuberculous glands more often than tuberculous tonsils. Even when there is a reappearance of the swelling the glands show more of a tendency to heal and the individual to enjoy health after the tonsils have been removed.

Sinus Infection.—S. Voorhees reports a case of primary infection of the bulb sinus and jugular in a woman of 56.

Myositis Ossificans.—A. R. Elliott reports a case of this condition occurring in a girl of 17. He notes that it has been thought to be a form of rheumatism, a trophoneurosis, a new growth, and a form of atavism, while Hutchinson claims it to be a morbid tissue perversion analogous to retinitis pigmentosa and xeroderma pigmentosum. None of these theories meets with acceptance, the present trend of opinion being toward the view that owing to some factor of congenital origin—indicated by so large a percentage of microdactylia and exostoses—the muscles seem to be endowed with very low resisting power and are consequently highly susceptible to inflammation from various exciting causes which ordinarily would not so operate, such as injury, chemical and bacterial irritants, etc. Combined with this low resisting power of the muscles there is a morbid disposition to aberrant bone growth which shows itself in the calcification and ossification of inflammatory products.

Fibroma of Nose.—W. J. Collins and J. D. Collins report a case of this condition secondary to rosacea, in a man 72 years of age.

Experimental Injury of Spinal Cord.—A. R. Allen as the result of his investigation reaches the tentative conclusion that in cases of fracture dislocation of the spinal column in the human subject in which there exists the symptom picture of transverse lesion of the spinal cord it would be well to perform the operation of laminectomy at the earliest possible moment, and, if the cord be not completely severed, to make a median longitudinal incision through the area of impact by means of a fine canaliculus knife in order to drain the injured tissue of the products of edema and hemorrhage.

Unusual Joint Cases.—By G. W. Guthrie. See MEDICAL RECORD, July 8, 1911, page 101.

Peritoneum-Grasping Forceps.—J. R. Eastman describes his modification of this instrument, whose advan-

tages rest in the ease with which the rubber tubing at the circular jaws may be replaced when worn or damaged in sterilizing, in the security of the grasp, and in its durability.

Bone Grafting.—F. A. McGrew describes a case in which bone grafting was resorted to as a means of filling a gap between two portions of a tibia.

Bone Transplantation for Pott's Disease.—F. H. Albee reports a series of cases in which a portion of the crest of the tibia was transplanted to furnish an internal splint and to bridge the gap in tuberculosis of the spine.

Respiration Valves.—C. C. Guthrie describes an improvement of his arrangement of valves for use especially in administering volatile anesthetics in laboratory experiments.

Excision of Tunica Vaginalis.—G. T. Tyler reports a case of painful testicle following gonorrheal inflammation in which the pain was relieved by the excision of the parietal portion of the tunica vaginalis which was bound down to the visceral layer by firm, dense adhesions.

Malta Fever in Texas.—E. R. Gentry and T. L. Ferenbaugh conclude from their investigations that epidemic Malta fever exists in Texas at the present time.

Control of Typhoid Fever.—L. L. Lumsden, W. C. Rucker, and A. W. Freeman conclude that the prevention of typhoid fever in the United States to-day depends on an improvement in the present methods of disposing of human excreta. Until all the people can be taught that the most dangerous material with which they come in contact in their daily lives is filth from human bodies, and until their sanitary habits are so changed that human filth is prevented from reaching human mouths, the prevention of typhoid fever cannot be consummated.

Medical Book Collecting.—F. H. Garrison and F. Neumann give some useful hints to collectors of old medical books for which Europe is the happy hunting ground. It is at the modest and obscure book stall of the Italian cities and other little frequented places that one can buy to the best advantage.

Salicylates in Rheumatism.—A. Lambert states that one can expect the full beneficial action of the salicylates only in true rheumatism. He has obtained the minimum of toxic and irritating effect from the use of a tablet made up as follows: Pure salicylic acid is mixed with sufficient sodium bicarbonate in excess, and with a sugar binder is made into tablets, so that on dissolving each tablet will give five grains of sodium salicylate. This is freely soluble in water with a pleasant acid taste and with a free elimination of CO_2. This seems to form a sodium salicylate in a nascent condition. By it a large amount of the active salicylate is gotten into the circulation at once in the least toxic and most effective form of the natural salicylate.

Herpes Zoster and Kidney Lesions.—M. Krotoszyner reports two cases of herpes zoster associated with kidney disease. The hyperalgetic peripheral zone of the kidney, according to Head, corresponds to that area of the integument innervated by the tenth and eleventh dorsal and upper lumbar spinal nerves. Within the last few months several cases of herpes zoster of this region, in connection with attacks of renal colic, have been reported. The author's cases illustrate the diagnostic value of careful investigation of Head's hyperalgetic cutaneous zones in all cases of abdominal colic of otherwise doubtful character.

The Lancet.

September 2, 1911.

Spinal Curvatures and Their Treatment by Physical Exercises. R. Timberg.
Omnopon: A Potent Adjuvant to Local Anesthesia. H. M. W. Gray.
Breast Feeding; the Value of the Test-Feed. E. C. Pritchard, H. R. Carter, and W. O. Pitt.
Pachon's Syphygmo-Oscillometer and Its Use in the Determination of Blood-Pressure, with Notes on the Theory of Oscillations. J. F. Halls Dally.
Fulminating Appendicitis; Presence of Liver Dulness; Ligature Temperature. F. W. Forbes-Ross and Q. Chalmers.
An Unusual Case of Intussusception. D. Wood.
A Dermoid Cyst of the Testicle. E. E. Hughes.

Spinal Curvatures.—R. Timberg describes the various physical exercises that are to be employed in the treatment of this condition.

Adjuvant to Local Anesthesia.—H. M. W. Gray states that omnopon, a watery solution containing nearly 90 per cent. of the soluble alkaloids of opium in chloride form, in conjunction with scopolamine, is apparently a safe narcotic, especially advantageous when used with local anesthetics in extensive operations in old patients.

Breast Feeding.—E. C. Pritchard, H. R. Carter, and W. O. Pitt have by means of accurate scales determined in a large number of infants the amount of breast milk obtained at each feeding. This amount is designated a "test-feed." The latter is a most valuable aid to the diagnosis of the ailments of breast-fed infants. It is mere guesswork to attempt to treat cases of this kind unless one knows how much milk the infant is receiving. Infants are often brought to the clinics who have been treated by drugs for constipation when the sole cause of the condition is starvation. Again, infants are often given supplementary feeds of cow's milk in amounts of four or five ounces when the test-feed proves that the amount they obtain from the breast is about one ounce—sometimes less. Under such conditions it is hardly surprising that cow's milk is found to disagree. As an aid to diagnosis and for accurately adjusting the amount of food given in supplementary feedings, or at the time of weaning, the test-feed soon becomes absolutely indispensable to those who have had experience of its advantages.

Pachon's Sphygmo-Oscillometer.—J. F. Halls Dally describes this instrument, whose use is based upon the estimation of movements or oscillations of the arterial wall at the level of compression.

Fulminating Appendicitis.—F. W. Forbes Ross and Q. Chalmers report a case of acute general peritonitis, due to the sudden onset of gangrenous appendicitis, and rescued by prompt surgical aid. The case presented a classical train of symptoms so typical of the condition, with the exception of the presence of liver dullness. The ligatures and sutures in the wall of the bowel and on the stump of the appendix are regarded as a cause of the post-operative febrile condition, so often seen for a limited period following the operation for removal of the appendix in septic cases.

Intussusception.—D. Wood reports a case of this condition in a child of two years, who after operation recovered in spite of the fact that there had been complete obstruction for two weeks before the child came into the surgeon's hands, and that there had been two grave operations involving resection of a considerable length of bowel.

Dermoid Cyst of the Testicle.—E. E. Hughes describes a case of this condition, which is considered extremely rare.

Surgical Treatment of Emphysema.—Pierre Delbet believes that some severe cases of emphysema are not due to changes in the lungs or bronchial tubes, but to alteration in the thoracic walls by which they become fixed and inexpansible. They are rigid in forced inspiration and dyspnea is extreme. The author presented the history of a patient operated upon by him by resections of five of the costal cartilages with great benefit. She was unable to lie down, had constant and severe dyspnea and attacks of suffocation. The good results of the operation were immediate. The costal cartilages in this condition have become inelastic and the enlargement of the upper part of the thorax becomes impossible. The articulations are normal. The patient presented a healthy and comfortable condition where previously she had been constantly cyanotic.—*Le Bulletin Médical.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

By THE INSURANCE EDITOR.

INCOMPLETE INFORMATION.

A special contribution on this subject is warranted in view of the difficulties experienced by the members of the home office staffs in securing full and complete reports. The busy practitioner, usually pressed for time, is too apt to make life insurance examinations with all possible haste, thereby missing important facts which a more searching inquiry would elicit or forgetting to record the answers to his inquiries in his report, all of which would probably be obviated if sufficient time were allowed.

An application, when signed and witnessed, becomes part of a regular contract, and it is not properly executed until each and every question is fully and correctly answered. It is the duty of the company to see that all requirements are satisfactorily fulfilled before allowing the release of the policy, especially for two reasons, viz., to protect the interests of those already holding policies by acquiring all possible information before assuming new risks, and to prevent any misunderstanding and chance for future trouble with the applicant himself in the event of the acceptance of his application. In order that this duty may be faithfully carried out, it is imperative to correspond with the examiner until all omissions, errors and incomplete information are properly supplied and corrected.

In a certain company which keeps careful records of the work of each of its examiners, an analysis of 100 cards taken at random from the files shows that in 1,279 consecutive examinations there were 239 in which omissions in answering the questions and 319 in which incomplete answers were found. As a result of such omissions and incomplete answers, the records in the same company show that about 50 per cent. of all applications reviewed by the approving officers during the year 1910 had previously passed over their desks one or more times, and were brought up again for further consideration on receiving information it had been necessary to ask for before final action could be taken. It is quite apparent from this statement that in order to correct these omissions and incomplete answers, the companies are compelled to conduct an enormous amount of correspondence and that there is a consequent heavy expense, much extra labor, and a great loss of time. Furthermore, the examiners themselves are put to considerable and unnecessary additional trouble in subsequently procuring missing information which could have been obtained when making the original examination. It may be added that, according to the records, examiners otherwise of undoubted skill may be numbered with those whose reports exhibit signs of haste and insufficient care.

Aside from the burden and expense to the companies, the delay resulting from the necessary correspondence gives rise continually to irritation on the part of the agent and applicant. The agent has learned from sad experience to dread delay in his business as it gives time for a change of heart in the applicant and a chance for his ever-ready rivals to wrest the results of his long-continued efforts away from him. Consequently he complains bitterly as soon as any obstacle tends to interfere with the prompt issuance of the policy. Realizing the difficulties of their solicitors in procuring business and finally placing the policies, the companies exert every energy to expedite and facilitate their work, though they continually find their efforts baffled through the receipt of incomplete information.

Examiners do not willingly and knowingly participate in causing all the troubles enumerated in this article. The individual examiner, when written to for some facts or details that should already have appeared in his report, will seldom realize that his shortcoming is one of very many. He is almost always eager to supply the missing data promptly, but even at the best he has caused a certain amount of inconvenience and delay. He has never had a good opportunity to learn how vast the proportions of these omissions and incomplete answers assume in the aggregate, and it would not occasion any wonder if he were to continue in the belief that these delinquencies are, after all, unimportant and of only occasional occurrence, unless he is enlightened in regard to this too common lack of thoroughness by some one in a position to speak intelligently on this subject.

The subject has been presented frankly with the confidence that every examiner who reads these lines will be glad to arrive at a better understanding of the situation and to exercise the utmost care and precision in making up his reports in the future if he has not already done so. The following suggestions are offered, as an observance of them will obviate much of the trouble referred to:

1. Allow sufficient time to make a thorough examination and careful inquiry.

2. Each question should be asked separately and the answer recorded at once.

3. Avoid the use of vague terms, such as "fair," "moderate," "child-birth," "change of life," etc.

4. Whenever the question can be answered intelligently by "yes" or 'no," these incisive monosyllables should be used rather than a lengthy answer, which may not be clearly understood.

5. When recording an illness, in addition to giving a clear description of the ailment, furnish a definite statement of the dates, duration of each attack if more than one, frequency of attacks, complications, and the date of last occurrrence and after effects.

6. An applicant will sometimes evade the question. This may be due to inability to concentrate or to a desire to conceal certain facts. The applicant will try to turn the conversation to other subjects, but the examiner should come back to his question, easily and tactfully, but persistently, until he has secured a definite answer.

7. Before forwarding the papers to the company always scrutinize the application carefully so that any omitted or incomplete answers may be discovered and corrected.

The Interstate Association of Medical Examiners.—At the meeting of this association, held at Spokane, Wash., on September 6, the following officers were elected: *President,* Dr. W. C. Cox of Everett, Wash.; *Vice-Presidents,* Drs. T. C. Witherspoon of Butte, Mont.; H. B. Luhn of Spokane, Wash., and Charles T. Cutting of Seattle, Wash; *Secretary,* Dr. L. L. Stephens of Seattle, Wash.; *Treasurer,* Dr. Frank M. Taylor of Portland, Ore. It was decided that the association unite with the American Association of Medical Examiners, but retain its identity as the Northwest Section of this Association.

Physician and Insurance.—L. Feilchenfeld communicates the deliberations of the Seminar für Sozial Medizin in Berlin on the above theme. Gottstein spoke of the importance of insurance for medicine and hygiene, the practical demands of insurance having often stimulated medical research. The insurance examiner is most interested in knowing why one individual is stricken with some disease, while another remains healthy. He must not simply determine that a given individual is healthy at the moment of the examination, but also assure himself that that individual's chances of a prolonged existence are good. Modern hygiene has had much to do with the practical questions of insurance. It has diminished mortality from infectious diseases. Yet it is indebted to insurance statistics for the knowledge of the professional dangers existing in many occupations. Insurance likewise has emphasized the importance of syphilis as a factor in shortening life, and the frequently permanent injury of blood vessels left by acute articular rheumatism.

Martius said that every disease results in a permanent damage to the organism, and leaves some defect. The latter, however, is only then of importance, so far as duration of life is concerned, when it involves an important organ of the body. History of past diseases must therefore be carefully entered into by insurance examiners. Another element in insurance is the greater or lesser constitutional strength of the organism, shown by adaptation to extra calls upon important organs and by resistance to infection. Dilatation of the heart after a long bicycle ride or the appearance of albumin in the urine after a long walk give evidence of a faulty constitution from an insurance standpoint. Hereditary influences are very hard to value. The mere existence of gout, diabetes, and obesity in an applicant's family may be of no influence upon his life expectation. Blindness, when total, excludes an applicant, yet color blindness may actually be a favorable factor in keeping the applicant out of several dangerous occupations.

Böhler gave some practical advice in the matter of medical examination of applicants for life insurance. In the first place, the medical examiner must take plenty of time for his work. He must take care not to excite the applicant who is already somewhat apprehensive of the ordeal. In getting the family history, one must inquire about pneumonia in the father, the character of the marital life in the mother, anemias in the sisters; these may point out the existence of an unknown tuberculous infection. In the physical examination, one should not forget to have the applicant march up and down the room to study his gait and effect of the exercise upon the pulse. Weight and height should be obtained by the examiner himself, not taken from any other physician's statement offered by the patient. The pulse frequency should be carefully noted; it may suggest an incipient tuberculosis. A full, slow pulse speaks against tuberculous infection, a soft and frequent pulse speaks in favor of it. Gastric "catarrh" is a frequent antecedent of this infection. The tuberculin test is not to be made except on direct request of the insurance company. Most important is examination of the heart. The pulse must be studied with the applicant sitting, standing, and after exercise. Arrhythmia is always suspicious, for it speaks for disease of the cardiac muscle. A slow pulse does not always mean disease of the heart muscle; Bismarck had a pulse of 40 all his life and yet reached very old age. Syphilis is always to be interprêted as a life-shortening disease. It is best to insure syphilitics early after infection and only for a limited number of years, so as to escape as much as possible the incidence of parasyphilitic manifestations.

Schönheimer spoke of insurance for physicians (most of his remarks are not applicable in American circumstances.) He especially insisted upon the necessity of insurance against damage suits. Any physician may become involved in a question of negligence or damages, because of another physician's blunder or misfortune. Badly interpreted *x*-ray photographs are a frequent source of false claims for damages. Insurance in such cases is further useful, because the insurance attorneys know better how to deal with those threatening suit than the average doctor. So far as accident insurance is concerned, a physician is a bad risk for the insurance companies. Small injuries may completely incapacitate him for work, his colleagues are always ready to certify to such incapacity, and he frequently neglects treatment or treats himself.—*Zeitschrift für Versicherungsmedizin*, July, 1911.

The Relation of the Medical and the Actuarial Departments.—C. B. Carr says that in the younger insurance concerns these two departments represent the forces of conservatism as against the aggressiveness and optimism of the agency department. In the beginning the work of the medical department is largely experimental. The medical director may have had insurance experience, but usually he comes from private practice and gives but a part of his time to his new work. He has no clerical assistance, has not studied insurance statistics and bases his selections upon individual impressions. He soon learns that it is easy to protect the company from high mortality if the protection of applicants by granting them insurance is not considered. Moreover, his reasons for denying applications soon appear to himself even erratic and inconstant. The medical director should seek all opportunities, therefore, to confer with the actuary department, not alone in individual cases, but in reference to the wide questions of insurance statistics and principles. This will lead to the formulation of determining the acceptance or refusal of applicants, founded upon principles and not individual and personal equation. In passing a risk, various advantages and disadvantages can be valued numerically in accordance with previously accepted values. Each individual case can then be brought under such valuations and a comparison with a hypothetic normal value will give the "figure of merit" or coefficient for each case. This coefficient will enable the actuary department to recommend the proper policy for the risk in question. Both the medical director and the actuary should be members of the so-called "insurance committee" which passes upon risks about which there is any question.—*Proceedings of the Medical Section, American Life Convention, New Orleans*, February, 1911.

The Agent and the Examiner.—Sexton thinks that the medical examination blank and the application blank should be separate documents and the agent should not get the medical report, the latter being forwarded to the medical department. The examiner should not allow the agent to be present during the medical examination. The applicant may not want to give a history of syphilis, for instance, in the presence of the third party. The agent, too, is interested in getting a favorable report and thus his presence disconcerts the examiner.—*Proceedings of the Medical Section, American Life Convention, New Orleans*, February, 1911.

Public Policy and the Sexual Question.—Eisenhodt contributes a lengthy theoretical and historical discussion on this theme, not adapted for abstracting. His conclusion is that both national welfare and the welfare of an individual, especially the prolongation of individual life, demand early marriages.—*Zeitschrift für Versicherungsmedizin*, June and July, 1911.

Simulation After Accident.—Windscheid writes a detailed account of simulation of mental deterioration after an accident accompanied by concussion. A careful physical examination and observation of the patient served to eliminate actual disease.—*Zeitschrift für Versicherungsmedizin*, July, 1911.

Book Reviews.

An Introduction to Therapeutic Inoculation. By D. W. Carmalt Jones, M.A., M.D. (Oxon.), M.R.C.P. (Lond.); Assistant Physician and Director of the Department of Bacteriotherapeutics, Westminster Hospital. Price $1.25. London: Macmillan & Co., Limited, 1911.

Few books have as yet been published dealing with the subject of vaccine therapy, and of these the present volume is one of the best. It is divided into two parts, the first dealing with the theoretical aspects of therapeutic inoculation which are presented in simple terms, and the second dealing with the practice of vaccine therapy. There are separate chapters discussing the value of this treatment in diseases of the skin, alimentary tract, respiratory tract, and one chapter on diseases of the joints and bone, lymphatic glands, genitourinary tract, and eye and ear. An appendix deals particularly with the technical details, which are substantially those employed in the laboratory at St. Mary's Hospital. These details are illustrated with the aid of large folded charts.

On Diseases of the Lungs and Pleuræ, including Tuberculosis and Mediastinal Growths. By Sir R. Douglas Powell, Bart., K.C.V.O., M.D. Lond., F.R.C.P., Hon. D.Sc. Oxon., M.D. Dublin, F.R.C.P.I., LL.D. Aberd. and Birm.; Physician in Ordinary to H.M. the King; Consulting Physician and Emeritus Lecturer in Medicine to the Middlesex Hospital; Consulting Physician to the Hospital for Consumption and Diseases of the Chest at Brompton, and to the Ventnor Hospital; Knight of Grace of the Order of St. John of Jerusalem; and P. Horton-Smith Hartley, M.V.O., M.A., M.D., Cantab., F.R.C.P., Late Fellow of St. John's College, Cambridge; Physician with Charge of Out-patients to St. Bartholomew's Hospital; Physician to the Hospital for Consumption and Diseases of the Chest at Brompton; Hon. Secretary of the Executive Committee of the King Edward VII. Sanatorium; Consulting Physician to the Daneswood Sanatorium. Fifth Edition With Illustrations. Price $6.00. Philadelphia: P. Blakiston's Son & Co., 1911.

This work, so familiar to students of the last generation, after a lapse of eighteen years since the publication of the fourth edition, has been completely revised and rewritten. This, the fifth edition, represents a labor of ten years, and the authors are to be congratulated on the production of a volume that comprises within the limits of its 712 pages the quintessence of present-day knowledge of diseases of the lungs and pleura and of mediastinal growths. The value of a work of this kind depends largely upon the experience and eminence of its authors, who in the present case, have brought to their labor a profound knowledge of their subject matter. This is illustrated in the thorough manner in which the entire subject of pulmonary tuberculosis is handled, nothing being omitted, from the discussion of *x*-ray diagnosis and the respective value of various climates to that of the merits of tuberculin therapy. The rarer diseases of the lungs, such as aspergillosis, come in for ample consideration. There are a large number of excellent plates and textual illustrations, and an exceptionally complete index.

A Manual of Surgery. For Students and Physicians. By Francis T. Stewart, M.D., Professor of Clinical Surgery, Jefferson Medical College; Surgeon to the Germantown Hospital; Out-Patient Surgeon to the Pennsylvania Hospital. Second edition, with 553 illustrations. Price, $4. Philadelphia: P. Blakiston's Son & Co., 1911.

It is no slight task to be able to present, as the author has done, a complete survey of the entire domain of surgery in one volume of 682 pages. This he has succeeded in doing by treating each subject briefly and with the omission of historical and bibliographical details. The completeness of this volume makes it available for the use of the student, while the general practitioner may find it a safe guide in diagnosis and treatment. Although the wide range of topics comprising modern surgery are described in a most condensed form, nevertheless this concentration does not sacrifice clearness or accuracy.

One Hundred Surgical Problems. The Experiences of Daily Practice Dissected and Explained. By James G. Mumford, M.D., Visiting Surgeon to the Massachusetts General Hospital; Instructor in Surgery, Harvard Medical School; Fellow of the American Surgical Association, etc. Price $3.00. Boston: W. M. Leonard, 1911.

The present volume is an admirable addition to the series of "Case Histories" that have amply demonstrated the didactic value of this method of presentation. The delightful literary style of Dr. Mumford enables the reader to approach any new book written by the well-known Boston surgeon with a sense of pleasurable anticipation. The discussion of many of the difficult problems in surgery by means of concrete instances enables the author not only to impart a lively interest to the subject, but also to introduce as comment many observations and inferences derived from his rich experience. The cases described are familiar to the busy practitioner, but each one is either a problem or an illustration of important features in diagnosis and treatment, a problem such as is usually presented to the surgical consultant.

The Principles and Practice of Bandaging. By Gwilym G. Davis, M.D., Universities of Pennsylvania and Gottingen; Member of the Royal College of Surgeons, England; Professor of Orthopedic Surgery, University of Pennsylvania, etc. Third edition, revised. Illustrated from original drawings by the author. Price, $1.00. Philadelphia: P. Blakiston's Son & Company, 1911.

In this third edition the text has been rewritten and the illustrations have been redrawn, so that it is practically a new book. The author, in simple language, describes all the bandages that are in common use, and by means of original drawings shows their method of application. Some years ago bandaging was a fine art, and there was much needless intricacy indulged in; now, the tendency is toward carelessness in the application of bandages, coupled with ignorance of their proper construction. The present work hits the happy mean between these two undesirable extremes.

Kurzgefasste chirurgische Operationslehre (Operationskurs). For Students and Physicians. By Dr. Ad. Oberst, First Assistant in the Surgical Clinic, University of Freiburg. With 232 illustrations, many in colors. Berlin: S. Karger, 1911.

This book is intended mainly as a guide to the various surgical operations to be executed on the cadaver. In addition to the directions for carrying out the various operations, attention is also directed to the topographical anatomy of the parts and the reasons for the various steps in the operation, and the indications for each. In order to appreciate the present-day developments of particular procedures, concise references to the historical development of the operations in question are also introduced. These features serve to distinguish the book from other manuals in this field, and deserve commendation. The book is very satisfactorily illustrated by photographs and original drawings, many of which are colored.

Unsoundness of Mind. By T. S. Clouston, M.D., L.L.D., F.R.S.E.; Formerly Lecturer on Mental Diseases in the University of Edinburgh; Physician-Superintendent of the Royal Edinburgh Mental Hospital, and President of the Royal College of Physicians, Edinburgh. With fourteen illustrations. Price, $2.50 net. New York: E. P. Dutton & Company, 1911.

This is a book written for the intelligent layman by an alienist of international reputation. The practitioner, who is not an alienist and who may not be familiar with the technicalities of the later works on insanity, may also find it interesting and profitable reading. Lawyers and judges who have much to do with insanity cases may use it as a book of reference. It is perhaps a little too general and written in too loose and popular a style to meet the requirements of the specialist himself. A knowledge of what constitutes unsoundness of mind, in a truly scientific or medical sense, is of the greatest value to the physician, the sociologist and the public at large, not only as an aid to its recognition when present, but also from the standpoint of prevention. It enables us to understand the differences and the relationships of mental disease or defect, on the one hand, and vice, inefficiency and crime on the other. Such a knowledge also enhances our interest in the study of history, biography and public and private character and morality. The author assorts mankind into eleven orders. Six of these he classes as legally sound in mind and five as unsound. The proportionate numbers of each class as estimated in the British Empire are stated. The classification is extremely interesting, but not entirely satisfactory from a scientific point of view. The chapters on the causation of insanity will be read by the laity with avidity; also those on early symptoms, borderland, speech, and unsoundness of mind and will-making. The American reader will rejoice with his British cousin that the bulk of the British population is made up of the "average man," legally sound in mind, and will sympathize with him in the possession of "100,000 cranks and anarchists." There is no reliable test between soundness and unsoundness of mind, but the subject is discussed in this book in such a way that it can at any rate be understood.

Clinique Chirurgicale. Anatomie, Diagnostic, Traitement, Opérations. Par le Dr. O. Laurent, Professeur a l'Université de Bruxelles, Chirurgien de l'Hôpital Saint Jean. Troixième Edition. Avec 1710 photographies et dessins. Price, 35 francs. Paris: Octave Doin et Fils, 1911.

As stated in the preface, the controlling method in this work is anatomical, synthetic, and clinical at the same time. The importance of an accurate knowledge of anatomy is emphasized in connection with every operative procedure. The wealth of illustrations with which this book is provided to an unusual degree enables the author to clearly indicate the anatomical foundations of every operation. The present edition shows that the author is alive to the latest advances in surgical technique, and his frequent references to the work of American surgeons, as well as those of Europe, show his familiarity with the literature. The difficult task of presenting in one volume a survey of clinical and operative surgery, as well as of topographical anatomy, has been accomplished by the author.

Handbook of Medical Treatment. A Guide to Therapeutics for Students and Practitioners: with an Appendix on Diet. By James Burnet, M.A., M.D., M.R.C.P., Edin.; Fellow of the Royal Society of Medicine; Lecturer on Practical Materia Medica and Pharmacy; Physician to the Marshall Street Dispensary, and Registrar to the Royal Hospital for Sick Children, Edinburgh. Price $1.50. New York: William Wood & Co., 1911.

In this handy little volume the author supplies the main facts of medical treatment. The various diseased conditions are taken up in alphabetical order, so that reference is easy. The methods of tratment indicated are sound, and will be generally acceptable; at times the author is somewhat dogmatic, but in a small handbook this is an advantage, especially when (as in the present case) the book is the outcome of wide experience. Though small in size, the volume will form a welcome addition to the library of the young practitioner.

The Medical Expert and Other Papers By Louis J. Rosenberg. New York: Broadway Publishing Company.

There are three very brief papers in this volume. The first, "The Medical Expert," is an address delivered before the faculty of a medical college which has since gone out of existence. The second, "Professional Secrecy," appeared in a medical paper which has since discontinued publication. The last, "The Metabolism of Morality," is here made public for the first time.

Neurasthenia. By Gilbert Ballet, Professeur agrégé à la Faculté de Médecine de Paris, Médecin de l'Hôtel Dieu; Président de la Société de Neurologie. Translated from the third French Edition by P. Campbell Smith, M.D. Third Edition. Illustrated with seven figures. Price $3.00 net. New York: William Wood & Co., 1911.

The present English edition of Professor Ballet's eminently practical, accurate, and clear exposition of a very common complaint, is taken from the third French edition, which contains a great deal of new matter. One of the new sections, of noteworthy interest and value, is that devoted to the differential diagnosis of affections to which the term neurasthenia is unfittingly applied. The author believes that half the number of patients presenting themselves to the neurologist as cases of neurasthenia are really "affected by some quite different complaint." If this is true, the need of an exact diagnosis is great indeed. A careful physical examination and mental analysis are necessary to eliminate the various affections which may simulate or accompany neurasthenic symptoms. What these affections are the author clearly points out and differentiates. The sections on treatment comprise two-thirds of the subject matter of the entire book, and these have been amplified and made more complete by additions to the chapters on psychotherapy, on diet, and other hygienic measures, and on the treatment of intestinal disorders and other associated conditions of frequent occurrence in neurasthenia.

A Textbook of Medicine. By G. Dieulafoy, Professor of Clinical Medicine at the Faculté de Médecine de Paris; Physician to the Hôtel Dieu; Membre de l'Académie de Médecine. Authorized English translation from the fifteenth edition of "Manuel de Pathologie Interne," by V. E. Collins, M.D., Lond., M.R.C.S., L.R.C.P., and J. A. Liebmann, Ph.D., M.A., LL.D. In two volumes. Price, $12. New York: D. Appleton & Company, 1911.

Those who are familiar with French medical literature have often remarked upon the absence of a translation of the deservedly popular treatise of Dieulafoy, while English versions of other less worthy French and German books have abounded. In France new and revised editions of this work appear with the regularity of the seasons. The main reason for the remarkable favor that the book has enjoyed in France is no doubt its personal character, which gives it a charm and an authority that no other compilation can possess. Like some of the older English and American treatises on the practice of medicine, this is based on the personal experiences of the author and is throughout illustrated with reports of cases from his own practice. It is therefore clinical rather than didactic in its description of various diseases and their complication, and so possesses the interest of all first-hand observations. The articles are grouped under the following comprehensive classifications: Respiratory system, circulating system, digestive system, urinary system, nervous system, general and infectious diseases, disease of the spleen, pathology of the blood, rheumatic and dyspeptic diseases, parasitic infection, diseases affecting the locomotor system, venereal diseases, the intoxications, and an appendix on therapeutics, the latter containing papers only on mercurial treatment, arsenical treatment, and injections of artificial serum. All of the chapters under these headings are readable and instructive and cover with much satisfactory completeness the subjects included. A pupil of Trousseau, Dieulafoy, whose lamented death occurred in August of this year, was his worthy successor—a keen observer, possessed of the discriminating judgment necessary for the diagnostician, the reasoning faith that makes the successful therapeutist, and the facile pen of a ready writer. All these qualities are in evidence in his treatise, which is the work of a master. The translation is well done, the illustrations are few, but good, and the typography, paper, and binding are all that could be desired.

Carl Spengler, "Tuberkulose und Syphilis-Arbeiten." Herausgegeben von seinen Schülern und Freunden. Davos: Verlag von H. Erfurt, 1911.

This is a work edited and published by Spengler's pupils and friends on the occasion of the distinguished phthisiotherapeutist's fiftieth birthday. An American physician, Dr. F. M. Pottenger, of Los Angeles, Cal., had the honor to write the introduction to the work. As can be foreseen from the two names—Spengler and Pottenger—the book represents largely that side of tuberculosis therapeutics known as tuberculin therapy. Spengler has the unique distinction of being one of the few men who have never ceased to use tuberculin; who, in fact, have used it constantly and largely since its introduction by Koch in 1890, and Pottenger has been for years and is still one of the most ardent American advocates of the tuberculin treatment. To Spengler's credit it must be said that he has constantly aimed at the production of a less toxic preparation than the original Koch tuberculin. Spengler has given to the profession no less than six different culture products for the cure of tuberculosis, namely, the P.T.O., P.E., A.T.O., P.V., T.B.V., and his latest and supposedly most efficient of all is the I.K.

It would be going too far to define all these culture products here, but it may be interesting to those not familiar with the latest product (I.K. "immune bodies") to read a brief description of it: It is obtained from animals which have been immunized to such an extent that they are capable of entirely absorbing large quantities of tubercle bacilli of a virulent and deadly type, without themselves developing tuberculosis. According to Pottenger, this product has, by scientific experiment as well as by clinical tests, shown itself to be of great value in the treatment of tuberculosis. Spengler claims that it contains both lytic and antitoxic bodies, and that its action combines that of a passive and active immunizer.

Besides this interesting chapter on I.K., the book contains all the most important works published by Spengler, dating from 1890 to 1911. Of particular interest are "Diagnosis of Closed (Early) Pulmonary Tuberculosis"; "Diagnosis of Tuberculous and Syphilitic Phthisis"; "Tuberculin Therapy in High Altitudes"; "The Hereditary Predisposition to Tuberculosis, Its Diagnosis and Treatment"; "Methods of Coloring Bovine and Human Tubercle Bacilli"; "Examination of Tuberculo-Syphilitic Sputum by Coloring Agents and Animal Experimentation."

Why a whole chapter should be devoted to the discussion of tuberculocidin, a culture product found and recommended by the elder Klebs some fifteen years ago, but the use of which has to the best of the reviewer's knowledge been long since abandoned in this country and abroad, is hard to understand. Aside from this seemingly useless chapter much can be said in praise of the book for the many valuable clinical and therapeutic hints it contains. Even to one who is not such an enthusiastic believer in tuberculin as Spengler and Pottenger the perusal of this book of 500 pages will prove instructive and interesting.

Society Reports.

AMERICAN NEUROLOGICAL ASSOCIATION.

Thirty-seventh Annual Meeting. Held at Baltimore, Md. May 11, 12, and 13, 1911.

THE PRESIDENT, DR. H. M. THOMAS OF BALTIMORE, IN THE CHAIR.

Thursday, May 11—First Day.

President's Address.—Dr. H. M. THOMAS in this address said that the circumstance that this meeting, the first that the American Neurological Association had held in Baltimore, fell on the hundreth anniversary of the announcement by Charles Bell of his idea of a new anatomy of the brain suggested the appropriateness of a few words of comment. Bell was regarded by many as the father of modern neurology, and this idea as the first evidence of his paternity. When in the latter part of 1811 Bell had printed in London for private distribution the "Idea of a New Anatomy of the Brain," a complete transcript of it had been published in the *Baltimore Medical and Philosophical Lyceum* for 1811, a fact that of itself had more than justified the appearance of this journal for the one year of its life, for this reprint had remained for many years, as far as he had been able to discover, the only actual publication of Bell's tract. If we were to date the birth of modern neurology from the time of Charles Bell, it might interest us to inquire for a moment what had been the prenatal state of this lusty infant, now one hundred years old. Neurology had advanced perhaps even less than the other branches of medicine and little more was known of nervous diseases than at the time of Hippocrates, Aretæus, and Galen. Clinically very few of the organic nervous diseases that we now know had been distinguished, for they were usually all grouped under apoplexy and palsy. Many conditions were recognized as affecting the brain, spinal cord, and nerves, as, for instance, congenital abnormalities, traumatic injuries, tumors, hemorrhages into the brain, and pressure on the nervous system from neighboring structures. Almost no attempt had been made to localize these processes within the central nervous system. The clinical observations of this period had often been accurate and detailed and one found the descriptions of cases so complete that there was little difficulty in the light of present knowledge in determining the probable position and character of the lesion. Should we not take council and under similar circumstances endeavor to make our records so objective that they would be intelligible one hundred years from now, even though our explanation of the findings might then seem as fanciful as those then given now seemed to us. The anatomists had studied the surface of the brain, most of its irregularities had been named, and much attention had been given to the ventricles and their connections. The cerebral circulation had been partially worked out and the peripheral nerves had been carefully dissected. Of the actual structure and internal arrangement of the brain little was known. The commissures connecting the two halves of the brain and spinal cord had been recognized and some observers had called attention to the decussation of nerve fibers at the anterior pyramids, but even this fact had been denied by many. Bell, while contemplating the seemingly unsurmountable complexity of the nervous system, had been struck by the constancy of the intricate connections of the peripheral nerves. This he had thought must have a meaning, and, as he believed that the nerves had special functions and were not each capable of performing all the functions, it occurred to him that this intermingling of the nervous filaments was a method by which the various parts of the body were supplied by nerves which differed in office. As the nerves of the special senses could be traced to definite regions of the brain he concluded that those areas were designed to respond to special stimuli and that it was in them that the different sense impressions were perceived; that is, that different functions were represented in different parts of the brain. If this arrangement were generally true, and if nerves having the same office always arose from the central nervous system, then it was only necessary to discover the functions of the various nerves and to trace them to their terminations within the central nervous system to reveal the function of the different parts of the brain. That Bell had at times misinterpreted his results and had been led to wrong conclusions did not detract greatly from the credit due him. The technical methods at his disposal were inadequate, and he had also been limited by the emphasis which he put upon anatomical results rather than upon experimental methods. Although he had extended and altered the details of his scheme he had never changed the fundamental idea, and one can imagine his delight could he return and see how it had lived, grown, and borne fruit.

Analyses of the Results of Dorsal Root Section in the Treatment of the Spastic State of Cerebral Diplegia.—Dr. L. PIERCE CLARK and Dr. ALFRED S. TAYLOR of New York presented this paper. Dorsal root section was being urged for the relief of at least three quite distinct conditions, namely, for pain, athetosis, and spasticity. The entire subject of radiculectomy was very much older than some would have us believe. Spastic muscular contractures prevented motor functions by offering more or less resistance to extension; they slowed the movement, and the movement once performed, had a tendency to persist beyond voluntary desire. A sort of physiological myotonus obtained as a result of the approximation of the two points of muscular insertion. The inhibiting function of the pyramidal tracts was independent throughout of the function producing spasticity. Many surgical procedures had been undertaken to restore the normal balance in the spinal reflex arc in diplegias. Early operation on the pyramidal tracts, even at their inception in the cortex, had left much to be desired. The majority of attempts to ameliorate the lot of the spasticities in the diplegias had been devoted to correcting the abnormal reflex arc in the spinal cord. The sensory part of the reflex arc was anterior in point of physiological time to that part of the motor mechanism which directly induced the spasticities. This and similar reasons induced Förster of Breslau to come to the same conclusion which the authors here stated. It was freely admitted that the degree of muscle tone in an extremity was determined by the sensory impression from the parts, and especially from the muscles. Tonic spasm might, therefore, be regarded as an augmented degree of this state, due to various causes. The impulses arising in the peripheral arc were collected from the muscle spindles. The motor part of the reflex arc was obviously beyond attack, for, while the contraction would be temporarily relieved, a complete palsy of the muscles involved would result. Neurectomy in the peripheral nerves proper could not be employed, as these consisted alike of sensory and motor nerves. Hence the posterior sensory roots near the cord, dorsal to the individual ganglion, were the point of operation if one wished to attack the sensory side of the arc. Even though ataxia and loss of reflex irritability should supervene in the operation, this state was much to be preferred to the spastic condition which it relieved. However, sufficient data were now at hand to show that neither mishap obtained in the new operation. Just what part and how much of the sensory stimuli might be removed to gain the desired amount of flaccidity was even yet not quite clear. It was reasonable to suppose that the sensory supply of the spastic muscles was approximately

from those nerves which also originated from the zonal areas of skin immediately overlying the muscles involved. Sufficient data were at hand now to show the operation was of little or no use in any spastic state where sensory defect existed. One might thus exclude all the forms of myelitis, and, in fact, all cord affections *per se*. The reason for this was not difficult to understand. The sensory defect added by operation was already in evidence in the disease itself before operation. The indications for the operation lay in those cases of pure pyramidal disease of cortical or subcortical origin. Little's disease was the disorder to which the operation in future would be largely limited. Even cases of infantile hemiplegia seemed to offer less prospect of betterment than in diplegia, as shown in Förster's, Gottstein's, and in their own cases. On theoretical grounds it would seem as though removing a part of the inflow of sensory impulses to the hemiplegic cortex might lessen or remove much of the cortical instability and thus make the operation of use to better the condition of hemiplegic epilepsy, but as yet data corroborating this view were not at hand. All diplegics showing painful and ineradicable spastic flexures exhibited good indications for this operation; in such their spastic state might be easily converted into flaccid palsies of normal anatomic rest. Unfortunately most of such cases presented such a degree of mental impairment that the important after-care and training were of little use. However, in diplegics of moderate intelligence with "scissors" gait or even "crossed-leg progression," the operation was of the greatest value. The value of the operation did not stop at a better gait for the little patient. The hope of further mental development in the diplegic and feeble-minded patient was in no small degree bound up in the freedom of movements of the extremities which was made possible after such an operation as here proposed. From a summary of all the cases, it might be said that in operating upon the lower extremity the posterior roots of all five lumbar, and the first two sacral entered into consideration. In a general way it sufficed in spastic palsy of the leg to resect the second, third, and fifth lumbar, and second sacral, in mild cases; or the third and fifth lumbar and second sacral if the spasticity was attended by adductor spasm largely, or the third and fifth lumbar and first sacral, if one desired to limit the completeness of the relief, for any cause. In the very severe cases, however, where there was extreme flexion of the knee, the second, third, and fifth lumbar and first sacral, or the first sacral, or the first, second, third, and fifth lumbar, and the first and second sacral should be resected. In brachial spasticities perhaps the best and completest results followed resection of the fourth, fifth, seventh, eighth cervical, and the first dorsal roots. It should be borne in mind that a part of the spastic conditions should be left as a physical brace for the paretic muscles.

Slow Compression of the Spinal Cord by Bone.—Dr. Pearce Bailey of New York said this might be a part of a general osteoarthritis and then have the same causes as that disease. It may also result from traumatic lesions of the vertebræ. The symptoms were those of slow compression with pain simulating the symptoms of tumor. Skiagraphs showed lesions in the bodies of the vertebræ, in the narrowing of the intervertebral foramina, and sometimes lesions elsewhere in the osseous system. Selected cases were suitable for operation.

Dr. James J. Putnam of Boston said he was not quite sure whether Dr. Bailey intended to make a distinction between cases of paraplegia and cases in which the symptoms might be explained by extensive irritation and compression of nerve substance. The first case that he saw was a good many years ago. The pain was so great and muscular wasting was so great and extensive, involving muscles supplied by both the lumbar and sacral nerves, that, while he thought it probably was cancer, nevertheless it occurred to him that the possibility of osteoarthritis was sufficiently great to justify treatment by immobilization. He was quite surprised then to see how much could be done by simple immobilization without any further operation.

Dr. B. Sachs of New York said that personally he would be in favor of preserving such well defined clinical types as the one now known as *spondylose rhizomélique*. Pathologically it might be related to those conditions of osteoarthritis. So far as osteoarthritis was concerned the question was of great interest, and the point they had learned at Mt. Sinai Hospital was that many of the symptoms which occurred in it were not only due to the compression by the bone, but also to exudative processes, which in nine cases out of ten were associated with the bone disease, so that the root symptoms were not due directly to compression by bone, but were often due to compression of the roots by an exudate in association with the bony formations.

Dr. G. L. Walton of Boston said he was impressed with the importance of investigating the spinal canal anteriorly in operation for cord tumor, and the possibility of an underlying osteoarthritis in supposedly uncomplicated trauma.

Dr. P. C. Knapp of Boston, Mass., said he would like to confirm what Dr. Sachs said about the dissociation of sensibility in these cases of bony disease of the spinal vertebra.

Chronic Hypertrophic Spinal Pachymeningitis.—By Drs. C. K. Mills and Edward Mercer Williams of Philadelphia. From the diagnostic point of view the subject of chronic hypertrophic spinal meningitis was of the utmost importance as indicated by the different opinions which had been given in the case which was the main subject of the paper and also in several other cases. They reported a case in a woman about 45 years of age, who suffered with recurring pain in the shoulder and arms, especially on the right side; who developed paralysis with atrophy in the distal portions of the upper extremities, impairment of power with exaggerated and abnormal reflexes in the lower extremities and also in the upper extremities, dissociated anesthesia, the changes in pain and temperature sense, especially the latter, being much more marked than those for the other forms of sensibility. A striking feature in the case was the great variability in some of the main features of the syndrome. Early in the history of the case the patient lost the ability to stand or walk, regaining and losing it again, and even late in the case the loss of power changed almost from day to day. Foot coldness and the Babinski reflex were present on one day and two or three days later were absent or very slightly marked. Even sensory conditions varied from time to time. Operation revealed marked thickening of the inside of the dura with flattening and displacement of the cervical cord, but the lesions were evidently too diffuse to warrant any attempt at removal of the thickened membrane. The patient died two or three weeks after the surgical procedure, and necropsy revealed widespread internal pachymeningitis most definite in the lower cervical and upper thoracic region, but present throughout the entire length of the vertebral canal. The cord was compressed and in some places invaded. The vessels both of the membrane and cord substance were sclerotic, changed in caliber, and in some instances obliterated.

Regeneration in the Sensory Root of the Fifth Nerve.—Dr. T. H. Weisenburg of Philadelphia read this paper, saying that in a case previously reported the patient, a man of 30, had pains in the face for seven years for which there were first performed peripheral operations,

and finally most of the Gasserian ganglion was removed and the sensory and motor roots cut. Two days after this the pains returned in spite of the fact that there was persistent anesthesia in the fifth nerve distribution. The pains were in the lower part of the jaw within the mouth, back of the tongue, and would radiate at times to the ear and down the throat to the shoulder, were especially severe on swallowing, and were not of the character that were present in tic douloureux. The patient lived for three years after the ganglion was removed. At necropsy there was found a cerebellopontile tumor which grew on the fifth nerve and compressed the pons and so separated the cerebellum from the former that it stretched the ninth and tenth nerves. During the man's life the lingual, the great occipital, and the cervical nerves were removed. The recurrence of the pain in this patient was undoubtedly the result of irritation of the ninth nerve. Physiologically the sensory distributions of the fifth and ninth nerves intermingled and therefore irritation of one should cause pain in the contiguous parts of the other. Moreover, no other conclusion could be arrived at because the distributions of the fifth and upper cervical nerves were excluded. In a study of the sensory and motor fifth roots distal to the tumor there were found dsitinct evidences of regeneration. In the motor root the regeneration of fibers was very marked, while in the sensory it was slight. These evidences of regeneration consisted in the formation of definite myeline sheaths and to a less extent of axis cylinders. There was hardly, however, enough regeneration to account for the return of pain. This finding was in total variance with previous experimental investigations, although not at all improbable, inasmuch as an opportunity to examine the fifth root had not been previously offered.

On Some Obscure Tumors Due to Midbrain Lesions.—Dr. Smith Ely Jelliffe of New York discussed the clinical and pathological aspects of some obscure tumors, due to lesions in the midbrain, particularly affecting the involuntary tonic arc. He also reported two cases: 1. A woman of 32, who had an apoplectiform stroke, was unconscious for a week, and later had paresis of the right side of the body, with slight sensory disturbance, some oculomotor palsies of the opposite side, and a more or less persistent hemitremor, resembling a paralysis agitans, with slight intention quality, of the side opposite the hemiparesis. Tremor was more noticeable in the upper than in the lower extremities. 2. This case was also a young woman, who fell suddenly, was not unconscious, but who had a slight hemiparesis of the right side, with possible diplopia, and possible hemianesthesia. She made a fairly rapid recovery, and was seen three months after the attack, suffering at this time only from a slight, but persistent, hemitremor in the right upper extremity resembling a paralysis agitans with slight intention quality. All trace of the hemiparesis and of the hemianesthesia had disappeared, save that the patient was somewhat stiff and awkward in the use of her right hand. She also had a right homonymous hemianopsia. The recent work of Marburg, von Monakow, Holmes, and Herz, all tended to show that hemiathetosis, hemichorea, and hemitremor were due to some interruption in the paths which have to do with the tonic innervation of the muscles. This arc might be interrupted either between the cerebellum and the red nucleus, or between the red nucleus and the thalamus, or between the red nucleus and the cortex; it might cut out either preponderatingly sensory tracts or preponderatingly motor tracts, and according to the proportion of tracts cut out and the precise localization of this cutting out the differences were to be accounted for. It would seem fairly certain that interruption of the rubrothalamic tracts tended to bring about the athetoid syndrome, that interruption of the rubrocortical, and corticorubro tracts brought about the hemitremor syndome; whereas the hemichoreic and hemiataxic movements usually spoke for a lower lesion, probably caudate to the red nucleus, and implicating the superior cerebellar paths close to the nucleus. There should be closer analysis as to the movements themselves, serial sectioning should be done, and the degenerations in the traits in question followed. Until both of these factors were carried out some uncertainty would persist in the interpretation of these posthemiplegic tremors.

Tumors of the Corpora Quadrigemina.—Dr. Herman H. Hoppe of Cincinnati, Ohio, read this paper saying that tumors involving and practically limited to the region of the corpora quadrigemina were not frequent. There was especially a dearth of literature of accurately observed cases, clinical and pathological, or the relations between lesions of the corpora quadrigemina and the functions of sight and hearing. The chief features of the case he reported were in brief: double vision, staggering gait, falling to the right, gradual loss of vision, ending in three or four months in total blindness, sudden attack of rigidity in all muscles, falling to ground without loss of consciousness, equal pupils, atrophy of optic nerves, no light response in pupils, all movements lost in the left eye except downward movement. All movement was lost in right eye except inward and downward, and there was slight ptosis of both lids. There was normal hearing. There was extreme static ataxia with retropulsion, so that the patient was finally unable to walk at all. Motion and sensation and reflexes were not affected. There were at no time forced position or forced movements. The anatomical structures in a position to be injured by the tumor growth would be the nuclei and roots of the fourth pair of nerves (injury to the third probable but not ascertainable), the posterior corpora quadrigemina (anterior probable), the termination of the lateral fillet, the superior cerebellar arms, and to a slight extent the left middle cerebellar arm, the spinaltectal, and thalamic tracts and the posterior longitudinal fasciculus. The other structures, as the fillet and pyramidal fiber system, and especially the sixth pair of nerves, would be subject to indirect compression and injury.

Lumbar Puncture in the Treatment of Aural Vertigo.—Dr. James J. Putnam and Dr. C. J. Blake of Boston read this paper. It was now about nine years since Babinski's observations on this subject were first published, and five years since the first cases of this series were observed. Babinski's interest in this matter grew out of his studies into the nature of artificial galvanic vertigo (with nystagmus and inclination of the head) in normal subjects, and it was of interest to note, as a sign that some change in the functional excitability of the labyrinth was brought about by lumbar puncture, that after the withdrawal of 15 c.c. to 20 c.c. of cerebrospinal fluid the reactions of the labyrinth to the galvanic stimulus were found to be no longer what they had been before. This applied, at any rate, to cases where these reactions had become changed in consequence of disease. Since Babinski's first communication a number of studies had been made, both by him and others, mainly in France but also in Germany, and results had been obtained which in general corroborated his statements. The experiences of Dr. Blake and himself had been of just the same kind with that of the other physicians. In brief, it might be said that the best cases were those where the symptoms did not indicate any very considerable disorganization of the labyrinth or any high degree of middle-ear disease, but rather an increase in functional excitability. Sometimes the favorable result was obtained at once, sometimes only after some days. Occasionally a second puncture was required. The amount withdrawn was usually 15 to 22 c.c. The only untoward

result thus far observed was headache, which might last some days or even a week or more. Good results were obtained in a considerable proportion of the cases.

Cases of the Dentate Nucleus.—Dr. E. E. Southard of Boston, Mass., read this paper saying that focal lesions of the dentate nuclei had been found in 19 out of 250 Danvers State Hospital cases personally examined in the gross therefor. These included 11 instances of focal sclerosis, 4 focal vascular destructive lesions, and 4 cases of dentate nucleus involvement in more extensive cerebellar lesions. The bearing of these lesions upon the diagnosis of organic dementia, general paresis, and dementia precox, in which condition the lesions were chiefly found, was tentatively sketched.

Dr. Smith Ely Jelliffe of New York said that Klist in his study of the hyperkinetic motility disorders had advanced the general hypothesis on physiological rather that anatomical grounds that the frontal rubrocerebellar tracts, or reverse tracts, were immediately involved in these hyperkinetic motor disturbances. Dr. Southard's suggestion was an interesting affiliation between the pathological disturbances in a definite portion of these pathological arcs with Klist's physiological hypothesis.

Dr. Southard said that Klist placed the lesions largely in the lower layers of the cerebral cortex, and in the thalamoneurons, thus approximating the claims which had been made for dementia precox in the lower layers of the cortex. His work was derived from work on chorea and on the midbrain.

The Sensory Tract in Relation to the Inner Capsule.—Drs. William G. Spiller of Philadelphia and Carl D. Camp of Ann Arbor, Mich., read this paper saying that different views were held regarding the position of the sensory fibers in the inner capsule. Some taught that they were posterior to the motor, while others held that the sensory and motor fibers were intimately mingled. In 1902 Dercum and Spiller published the study of a case in which hemianesthesia had existed about nine years, and degeneration was found confined to the posterior part of the posterior limb of the inner capsule and to the posterior part of the lenticular nucleus. They now reported another case of the same character. As in both these cases, studied by microscopical serial sections, the lesion was very sharply defined, the separation of the sensory from the motor tract seemed to have been clearly demonstrated, and it was concluded that the sensory fibers were posterior to the motor although some of the sensory fibers might pass through the posterior part of the lenticular nucleus.

A Pathological Study of Türck's Bundle.—Dr. John H. W. Rhein of Philadelphia said the exact anatomical relation of the fasciculus of Türck was still a matter of dispute. He had studied two cases. In the first case the three temporal convolutions were entirely atrophied or degenerated and the atrophy cut in large part the optic radiation of Gratiolet and the fasciculus longitudinalis inferior. The fasciculus of Türck was totally degenerated in the foot of the peduncle, though there were a few stained fibers demonstrable in the subthalamic region and some fibers which were probably not longitudinal ones in the foot of the peduncle. The second case showed atrophy of the middle portions of the second and third temporal convolutions with degeneration of the white matter of the first temporal convolution and slight atrophy of the posterior portion of the first temporal convolution. The fasciculus longitudinalis inferior and the optic radiation of Gratiolet were markedly implicated at the level of the subthalamic region. The fasciculus of Türck was in the main preserved, though its volume in the foot of the peduncle was perhaps reduced somewhat. It seemed from this that fibers from the occipital lobe did not figure greatly in the formation of the fasciculus of Türck, nor did the fibers from the middle portion of the second and third temporal or the posterior part of the first temporal convolution.

The Deviation of the Tongue in Hemiplegia.—Dr. Ernest Jones of Toronto, Canada, had investigated 313 cases of hemiplegia from this point of view. In 104 cases the tongue was protruded toward the paralyzed side (typical), in 40 toward the opposite side (atypical), *i.e.* the contralateral genioglossus was paralyzed nearly three times as often as the homolateral. In 67 cases the tongue could be put into the cheek on the side of the lesion more easily than into that of the side of the paralysis (typical), in 21 cases the reverse was the case (atypical), *i.e.* the contralateral styloglossus was paralyzed more than three times as often as the homolateral. The two atypical symptoms did not tend to occur in the same cases, so that four sets of cases are to be distinguished. There was every reason to believe that the genioglossus, the muscle of most significance in this connection, was represented in both hemispheres. The experimental evidence seemed to show that it was briefly represented in the homolateral hemisphere, and the clinical evidence that it was chiefly represented in the contralateral. Beevor's explanation of lateral deviation was incomplete, and did not account for all the facts just stated. A final explanation was impossible until the course of the corticohypoglossal tracts was more fully elucidated. The four symptoms just mentioned could probably be accounted for by a varying implication of the four different corticohypoglossal tracts that proceeded from each hemisphere; this might depend either on a variation in the crossing in different cases or on a variation in the position of the lesion.

Dr. T. H. Weisenburg of Philadelphia said that in the case of tumor of the cerebellopontile angle in which there was irritation of the ninth roots, the tongue was deviated to the side of the tumor. In this man there was spasm of the tongue and often when he would open his mouth you could see the tongue in spasm, always to the side of the lesion and never beyond the lips.

Dr. Harvey Cushing of Baltimore, Md., said he had a feeling that the tongue got its sense of position from the position of the jaw, and deflection of the jaw might mean that the tongue was getting its sense of position directly from the jaw, and, even though the tongue was deflected, it was really in position when compared with the deflection of the jaw. After trigeminal neurectomy the tongue deflected. The tongue sought its sense of position in the mid-line when it appeared to deflect.

Report of a Case of Beriberi from a Small Epidemic Occurring in Newfoundland.—Dr. John Jenks Thomas of Boston read this paper reporting this case of a man 31 years of age. Fifteen months ago the patient noticed that his legs were weak, followed by paralysis with double toe-drop without pain. There were digestive distress and tachycardia; they were followed by slow improvement. There was an absence of infectious diseases or intoxication to explain the symptoms. Twenty-five similar cases occurred in the small town, one resulting fatally. There was an absence of the usual factors considered responsible for this disease.

On the Relative Frequency of Traumatic Neuroses in the United States and Their Relation to the Employers' Liability Act.—Dr. B. Sachs of New York read this paper saying that it was probably noted that as a result of the social tendencies of the day, there was a general disposition in various States to pass what was known as the Employers' Liability Act, which provided that if an employee was hurt, whether it was due to the fault of the employer or not, he was to be indemnified. This law had been declared unconstitutional by the highest court of New York, but in other States laws similar to this had been passed, and he had no doubt that means would be

found to modify this law in such a way that it would be declared constitutional. In Germany and France and Switzerland they had such a law, and the result had been that the physicians, and particularly the neurologists of Europe, had been overrun and they had been almost maltreated in the abuse they had received in the way of determining the exact percentage of disability caused by accidents. They were not only called on dozens of times and asked what degree of disability existed, but Nonne wrote to him not long ago from Hamburg stating that when he was over here he was surprised to see so little traumatic neurosis, and he believed that the large percentage of traumatic neuroses found in Germany was due to the German Employers' Liability Act. In Germany the condition was known as traumatic neurosis, not neuroses, but a single traumatic neurosis. That disease was practically unknown in this country, and when we called it so we saw it only in connection with the suits entered against railroad companies, etc. These liability acts had not as yet been passed. There would yet be a period of a year or two in which the normal condition of things would exist. He would suggest that the men in various States determine the frequency of this condition. He was quite certain that with the present socialistic tendencies in this country these acts were going to be passed, and that in future years we would see whether this traumatic neurosis had been increased by the passage of these laws, and by comparing statistics of coming years with past years he thought we would be able to make some valuable deductions. He thought it would be a good plan to have at least one subject at their next meeting in which all the men would take more or less interest.

Dr. Russell of Canada said they had the liabilities act in Canada and he felt quite sure that the number of traumatic neuroses had increased remarkably in the last year since the Employers' Liability Act had come into force. He was quite sure the members of the association would see the same thing in New York when that bill was passed.

Dr. Ernest Jones of Toronto, Canada, said the frequency of traumatic neuroses had perceptibly increased in Canada since the passage of the Employers' Liability Act.

Dr. Hugh T. Patrick of Chicago, Ill., said he thought each member of the association, after another year of observation, could bring a statistical contribution. As a matter of fact, he did not think that any statistical contribution was in the least needful. Any man who had carefully studied as many as fifty cases or less of traumatic neuroses could arrive at a conclusion which seemed to be absolutely inevitable, particularly if studied in a broad sense and not in a purely technical neurological way. If he had studied the temperament of his patients and had been a little broader and applied the principles of human nature, human motives, and human susceptibility, he arrived at the conclusion that the Employers' Liability increased the traumatic neuroses so long as there was any prospect of recompense for injury received, whether that injury were a matter of fact, or whether it were only a matter of fact in the estimation of the patient.

Friday, May 14—Second Day.

The Etiology of the Occupation Neuroses and Neuritides.—Dr. W. E. Paul of Boston read this paper, saying that writer's cramp had been chiefly studied for a hypothesis of the etiology of the occupation neuroses. The symptom almost exclusively considered was cramp. The extensive symptomatic variations had received scant attention from the etiological standpoint. Paradoxical and contradictory statements were very numerous. A possible peripheral etiology was briefly and lightly dismissed. The hypothetical central theory had been incorporated into the definition. The symptom of cramp and the legend that cessation of the occupational act relieved cramp and permitted the muscles affected to do anything else perfectly had necessitated the central hypothesis; the fact that cramp might occur later in the left hand, put to the same use, was assumed to bolster up the theory of a central etiology. There had been emphatic dissenters from the belief in a central pathology, who had asserted the etiology was peripheral. Other occupation neuroses had the same etiology as writer's cramp which was universally chosen as the type. If undoubted peripheral nerve symptoms developed, a new classification was invoked. The symptomatology presented a greater variety of symptoms. The individual views of authors as to what was comprised in the term "occupation neuroses" were far from uniform. Experimental work showed that peripheral nerve injury or trauma could give rise to practically all the symptoms of an occupation neurosis. The majority of the symptoms could not be explained by the central hypothesis. Ten cases were reported in which the rule that all other acts than the occupational acts were done fully and freely did not hold. Also 200 cases were analyzed from the records of the Massachusetts General Hospital which demonstrated the frequency of pain located in many cases near or in joints. The impacts, squeezings, tensions, and stresses of excessive physiological functioning, acting on muscle tissue, or on sensory and motor nerve structures which run in the soft tissues and terminate in muscle, tendon, joints, or fasciæ, brought about neurolytic or myelytic changes responsible for the occupation neuroses and so-called neuritis and occupation pain.

Dr. George L. Walton of Boston said that Dr. Paul's paper was a timely plea for further knowledge of the terminal nerve expansions and their reaction to external influences. It was to be hoped that it would stimulate physiological study of this part of the neuromuscular mechanism. At present the whole study was theoretical and the most to be claimed for this theory was that it offered more logical explanation of the phenomena than the theory which we previously had obtained. It was perhaps too sweeping entirely to deny cerebral exhaustion as a factor, but it should be remembered that the higher cerebral centers had all to do with such movements as have become sufficiently constant to produce an occupation neurosis—such movements were largely automatic and relegated largely to the lower centers which could stand an enormous amount of work.

Dr. James J. Putnam of Boston said that Dr. Paul had done a real service in calling attention to this aspect of these disorders and he heartily concurred in what he had said. He would only add that he thought he ought to form the habit of realizing that the mental pictures which the patient formed of the difficulty itself reinforced the result.

Dr. J. Ramsay Hunt of New York said that his feeling in regard to the occupation neuroses was that we were in much the same position as we were in in regard to the term neurasthenia, that a great many cases were classed as occupation neuroses or occupation neuritides, which properly speaking did not belong to that group. He felt that there was a clear distinction between the occupation neuroses of central origin and the occupation neuritis which was entirely a peripheral affair, and he thought it complicated the subject very much to attempt to fuse them in any way. Of course there might be a peripheral factor in the production of a central neurosis just as there was in the production of a habit spasm which was a central neurosis, and also there was no reason why the occupation neurosis should not be combined with an occupation neuritis in a given case or given different cases, but he believed that they should be kept quite distinct.

Dr. M. Allen Starr of New York said this subject was to him a very interesting one, for at his clinic for many years he had a very large variety of occupation neuroses. They were indebted to Dr. Paul for having brought forward the peripheral theory and for having put it in a very interesting way, but as he looked back upon his experiences, both in the clinical cases that he had seen and in a large number of cases of pianists seen in private practice, there were certain points which had impressed him in a way to make him differ somewhat from Dr. Paul's general conclusion that these were all peripheral cases. He would be much more inclined to agree with Dr. Hunt that it was a mistake in any disease to limit one's view to a single standpoint. There was no reason why there should not be many cases that corresponded to Dr. Paul's idea that they were of a distinctly peripheral nature due to injury of muscle plates, but it seemed to him, on the other hand, that there were cases which were distinctly indicative of a central origin of the disease.

Dr. Alfred Gordon of Philadelphia said that several years ago he made a systematic study of a series of cases of pure occupation neuroses, telegrapher's cramp, pianist's cramp, etc., and that he obtained very satisfactory results with Bier's method. A circular band was applied around the wrist and kept on for an hour twice a day regularly. The patient was allowed to resume his work. The results were quite favorable. It was also true that in a series of cases he obtained good results with complete rest.

Some Effects of Underfeeding on the Growth of the Brain.—Dr. Henry H. Donaldson of Philadelphia said that underfeeding sufficiently severe to stop or nearly stop the increase in the growth of the brain during the active period of the albino rat did not modify the maturing processes in this organ, as indicated in the change in the percentage of water, nor did it modify the formation of the medullary sheaths, as shown by the usual methods for demonstrating this. These two processes continued under conditions which stopped the increase of the brain in size.

Differential Diagnoses Between Manic-Depressive Insanity and Dementia Præcox.—Dr. Alfred Gordon of Philadelphia read this paper, saying that a careful analysis of every phase of the mental affections in four cases observed for several days led him to the following conclusions: In spite of the fact that every one of the four patients presented at one time alternating phases of maniacal and depressive outbreaks and at another time symptoms of dementia pæcox, there were certain features which constituted very important differential diagnostic elements, to wit, if in an individual affected with outbreaks of depression and exaltation, each characteristic of mania and melancholia, a change of his affective and intellectual faculties, and particularly of the first, was observed, the presumption would be in favor of an eventual dementia præcox. If the patient began his mental disorder with symptoms of dementia præcox and later developed the picture of manic-depressive psychosis, but one following closely the other, the latter might carry with it some important features of the first and these very same features would present then a very significant diagnostic element.

The Early Symptoms of General Paralysis.—Dr. Phillip Coombs Knapp of Boston read this paper, saying that it included a study of 100 cases of general paralysis in 90 men and 10 women, seen on the average a year and eight months after the onset of morbid symptoms. Twelve were cases of taboparalysis. A comparison was made between the symptoms which were reported as the initial symptoms of the disease and the symptoms presented at the time of examination. Sensory symptoms, headache, pain, and paresthesia were the commonest initial symptoms, although of less relative frequency later in the disease. Apoplectiform and epileptiform attacks were relatively more frequent as initial symptoms than as symptoms of later onset. Motor symptoms were not very common at the beginning of the disease, but were almost universal later, occurring in 87 cases. Nearly every patient presented alterations of the knee-jerk (96 cases) and of speech or handwriting (93 cases). Mental symptoms were noted among the initial symptoms in 49 cases. There was no case which did not present either alterations in the knee-jerks, or in the pupils, or in the speech, or handwriting. There were 3 cases in which no mental disturbance was detected, and 12 more in which the mental disturbance was insignificant. This warranted the classification of paresis among the diseases of the nervous system in general rather than as a distinctly mental disease.

Dr. H. R. Stedman of Boston said that Dr. Knapp made a plea for the preponderance of physical over mental symptoms in the prodromes of mental disease, but he was very far from being convinced. General paralysis was primarily and essentially a disease in the cortex, whose highest functions were the mental processes. Therefore it seemed to him to go without saying that the mental enfeeblement must be present. There must be some shade or degree of enfeeblement in the beginning of general paralysis. Then, again, the average person was far less likely to notice and remember and give due weight to the purely mental, the minor mental changes like impairment of attention and slight changes in character and disposition and all that, while on the other hand the physical changes, like tremor and the pupillary changes, while far more noticeable and tangible, would be far more likely to make an impression upon him and be remembered.

Dr. Morton Prince of Boston said that Dr. Knapp had spoken of the relative difference in time in the onset of the sensory and mental symptoms. He thought there was a very great fallacy in statistics of this kind. Dr. Knapp said he depended upon the statement of the patient or of the relatives. That the patient could not give an accurate account in a case of insanity went without saying. A number of cases came to his mind where the relatives said that the person was a very highly intelligent individual; they were unwilling to admit that any mental symptoms had developed, partly because of their unwillingness to face the truth, partly to find some way of explaining those symptoms.

Dr. G. L. Walton of Boston said he was thoroughly in accord with Dr. Knapp's position. He did not deny the existence of delicate and elusive mental symptoms in the early stages, but agreed with Dr. Knapp that the mental symptoms were far less prominent than the physical signs at the onset. The practical bearing was that if a patient presented himself with a mental condition suggesting paresis, if there were no pupillary or other reflex disorders, no trouble in speech or writing, no tumor, and no history of apoplectiform or epileptiform attacks, or other of the physical signs of that disease, the chances were overwhelmingly against the diagnosis of paresis.

Dr. M. Allen Starr of New York said that a few years ago Dr. Hunt went over the records of 200 cases from his clinic as a result of which study many of the facts which Dr. Knapp had presented to them could be confirmed. There was one fact that came out in that analysis which had not been brought forward here, that was, among the early mental symptoms they found it was very much more common to have a period of mental depression than of exaltation. It seemed to him that a study of his cases confirmed the statement of Dr. Stedman that, when they began to fail, it was the highest

centers that went first and that in these cases it was not quite fair to make their estimation of the early symptoms from the statements of the patients when the disease had developed, or from the statement of relatives, notoriously inaccurate witnesses, but from the statement of their own mistake of cases which they had seen and not been able to make a diagnosis of, and which subsequent events had shown that they had before them cases of paresis.

Dr. C. L. Dana of New York said Dr. Knapp had brought forward a subject of great importance. But perhaps Dr. Knapp had ignored the fact that in those early symptoms which he described as early symptoms of paresis both the sensory and motor and the mental were all three important symptoms of a luetic disorder of the central nervous system. His experience was that paresis usually, or often, attacked a person first through a condition which we called luetic neurasthenia or luetic depression and more rarely luetic mania. If the disease goes on, as it usually did, then paresis developed; but if proper treatments were applied the sensory symptoms and motor symptoms were sometimes arrested and no paresis ensued. Now the test by which they could determine whether a luetic condition was one of luetic ischemia or early paralysis was to be found ultimately in a careful study of the blood and cerebrospinal fluid, and already they had gotten pretty nearly to the formula by which they could tell.

Dr. Theodore Diller of Pittsburg, Pa., said he was sure there were many cases of paresis with physical signs which were perfectly well developed before the appearance of the mental symptoms.

Dr. Ernest Jones of Toronto said there seemed to be involved four distinct classes of facts: first, as to which symptoms were first to occur; second, those which were first to be noticed by the patient; third, which were the ones leading the patient to complain and to seek medical treatment; and, fourth, which were the most constantly found when the case came under observation by the physician. His experience in regard to the four classes of facts, based on several hundred cases studied from the point of view of symptoms, was that the first symptoms to be noticed by the patient were physical, but the first symptoms of which they complained and which lead them to seek advice were the mental kind, and when the physician saw the case the mental symptoms were the most constant and pronounced.

Dr. Henry A. Cotton of Trenton, N. J., said that from the standpoint of the hospital physician he thought one would see in some cases the physical signs appear first, and in others the mental signs appear first. He believed that unless paresis was in a stage where there could be no mistake as to diagnosis one should make lumbar puncture, which in the early stages would show a lymphocytosis where one hardly suspected general paralysis from the physical or mental signs.

Dr. Knapp, in closing, said he did not think they had any data whatever which enabled them to say what symptoms were the first to appear in general paralysis. Hardly any one of them had observed a case with sufficient accuracy over a sufficient length of time to be able to say that they had seen the case from the first day paresis began to develop and followed it and noted all the symptoms until paresis had been definitely established from the diagnostic point of view. He had tried to make it clear that the statements of the relatives were of extremely little value. The data as to the initial symptoms which he had presented could not be accepted as definite and absolute facts. They were simply what the patients and their friends had reported. We did not know which were the first symptoms in the actual development of the disease. We must depend partly on the statements of the relatives and patient before we saw the patient.

Imperative Pains.—Dr. Frank R. Fry of St. Louis, Mo., read this paper, saying that the various psycopathic conditions presented characteristic reactions to pain. For example, in the hysterical patient the pain was focussed in some member or locality of the body and the patient was bewildered by the intensity of it. On the other hand, the hypochondriacal patient with his pain referred to a viscus had a very definite conception of his imaginary malady and the pain which he suffered was to his mind a part of the supposed malady. The incessant complaint of the nerasthenic of serious pain might be contrasted with the behavior of the melancholic who bore his pain in silence and in terror. The paranoid patient disturbed with dysesthesiæ believed some evil influence was working through them; while the psychasthenic carefully sought to convince you that he had a pain, that it was of long standing, that he did not know what produced it, but that it was a grievous thing and that he would like to have it cured. It was in this latter class particularly that they found the insistent variety of pain which he had demonstrated "imperative." He believed that this kind of pain occurred along with the obsessions, tics, and compulsive phenomena of the psychasthenics. In attempting to analyze psychic symptoms they should keep in mind the fact that one fundamental psychopathic trend or tendency might dominate the picture, but at any time there might appear the symptoms of other tendencies to obscure or distort it. Hence it was more important in each case to learn all of the patient's temperamental and psychopathic tendencies than to hasten too soon to classify him or his malady. For instance, a patient often started out with neurasthenic symptoms and afterwards developed hysterical signs. Again, it was sometimes difficult to draw the line between mere neuritic pains and psychic pains. In many of these cases there was a neuritic irritation, but there was at the same time present, as afterwards developed, a psychopathic tendency so marked as to make the pain symptoms and the consequent mental picture out of all proportion to the local irritation. It was only after studying many of these situations carefully that we could decide whether the poor resistance to pain was physical and local or whether it was mental. A familiarity with the possible pictures of mental pain was the only means of differentiating conditions.

Dr. G. L. Walton of Boston said the factor of fear was important, that the imperative nature of pain in the psychoneurotic resulted from his obsessive insistence on absolute safety and comfort.

Dr. Theodore Diller of Pittsburg, Pa., referred to the psychic or mental pains seen in the so-called traumatic neuroses. He had engaged in an investigation of this subject and after reexamination of old patients after from eight to ten years, he had been very much struck with the existence of pains in these conditions.

Dr. Charles K. Mills of Philadelphia said there was a class of cases in which imperative pains were a striking feature which he thought should receive more attention. They were cases which seemed to him to distinctly deserve the designation of hallucinations of pain. They were very serious cases. Two patients in whom he had observed these pains were men of very high intellectual attainments; one was a clergyman, a writer, a man of distinction in his own profession, and in the world of literature who, in middle life or perhaps a little later, became the victim of these hallucinations of pain. Surely they were imperative pains. No examination was made or could be made so far as he could tell in this case which revealed a physical basis for the pain. Another case which was well known in Philadelphia was that of a man who had been seen by a number of neurologists, surgeons, ophthalmologists, and others—a man of great

ability and distinction, a writer and teacher, who had suffered for more than ten years. His description of the pains was very much like the description given by a tabetic patient. All sorts of opinions had been given of neuritis, tabes, concealed except for this manifestation, the pains due to fibrous indurations, bone conditions, of phlebitis, and so on.

Dr. Archibald Church of Chicago, Ill., said they would find these ideas of pain, yet with no special physical basis, but with the fear of physical disability. They were absolutely analogous to, if not identical with, the phobias of psychasthenia. He had had the good luck in the last three months of dissipating some very protracted fears of this sort by the reiteration of suggestion, just as they undertook to combat the ideas of psychasthenics. This pain was associated almost invariably with some uncomfortable or unpleasant physical experience, and it therefore persisted, the starting point of suggestion having taken place in the ordinary way.

Dr. M. Allen Starr of New York said that imperative pains in the nerve distribution were very difficult to diagnose. He had had an experience of that kind in a patient who was struck in the inguinal region, and he came to the conclusion that the patient was suffering from psychasthenic pain in the nerve distribution. The patient stated that he was much relieved by the ethyl chloride spray, but the pain invariably came back. He then determined to find the effect of suggestion. He had ethyl chloride applied well upon the abdomen. The result was quite as good as before. He had entire relief of all this pain, even for a long time. Of course the pain recurred. These pains, which seemed to be in the nerve distributions, were more difficult to diagnose than were the more diffuse pains under discussion. It was generally recognized that these cases were often greatly benefited by hypnotism. He had seen the pain disappear after hypnotic suggestion.

Dr. W. E. Paul of Boston believed with Dr. Mills that in some cases the pain verged on the hallucinatory character. A man of 48 had a spot of pain in the left buttock. It was a constant pressing, boring pain limited to this single small cavity. It had not stopped a moment for 15 years. He was conscious of it as soon as he got up in the morning. He was a lawyer. His financial interests were varied and large and he was fully alive to them, but he complained that the zest and spirit of these were taken out by his affliction. In other respects his health was good.

Automatism in Insanity.—Dr. Theodore H. Kellogg of Riverdale-on-Hudson, N. Y., read this paper, saying that toxic insanity was accompanied by active automatic states. In all states of torpor in the acute psychoses there was habitual automatism. Automatism consisted of rocking of body, friction of body, beating the air, rhythmical gestures, insane antics. In more passive forms the patients continuously maintained the erect position or recumbency. These fixed positions were resumed as soon as forcible changes were made. Some repeated automatically any question put to them; some could read aloud without the remotest conception of what they were reading. In the case of young children the presence of automatism would enable the physician to make the diagnosis. In alcoholic dementia the automatism might point to the cause; in the climacteric the differential diagnosis between prolonged attacks of aberration which were recoverable from and those which were not recoverable would be denoted by automatism.

(To be continued.)

Nephritis Following Parotitis.—Cannata, in reporting a case of this condition states that there are forty instances reported in the literature, of which very few occurred in children.—*La Pediatria.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

New Jersey State Board of Medical Examiners.

June 20 and 21, 1911.

ANATOMY.

1. Describe the endocardium.
2. Give origin, branches, and parts supplied by the musculospiral nerve.
3. Name five muscles of the shoulder and arm. Give origin, insertion, and action of any *one* of the five.
4. Name the muscles attached to the great trochanter of the femur.
5. What are the functions of the superior mesenteric veins?
6. Mention an anastomosis between the portal and systemic veins.
7. Name, locate, and describe the largest of the cranial ganglia.
8. What nerves supply the knee-joint?
9. In what respect do the pulmonary differ from other veins?
10. Describe the facial vein. Name its tributaries.
11. Describe the long saphenous vein.
12. What muscles (*a*) elevate, (*b*) depress the os hyoides and the larynx?
13. In fracture of the shaft of the radius near its center, what muscles are involved in displacement of the fragments?
14. Name and describe the different glands of the stomach.
15. In what way do the axillary and deep cervical glands communicate with each other?

PHYSIOLOGY.

1. What chemical change is necessary for blood coagulation?
2. Is the alkalinity of the blood increased or diminished by exercise, lactation, or digestion, and why?
3. State the normal amount of blood in a man weighing 160 pounds. How is it renewed after hemorrhage?
4. What is absorption, and by what process is it accomplished?
5. What conditions favor, and what conditions retard, absorption?
6. State the origin and function of lymph. Is it coagulable, and why?
7. What tissues and organs are developed respectively from the ectoderm, mesoderm, and entoderm?
8. What are the Wolffian bodies, and what becomes of them?
9. Discuss the corpus luteum. Does it indicate pregnancy? Explain.
10. What principal centers are located in the medulla?
11. What are the functions of the brain membranes?
12. Compare the functions of the white and gray matter in the encephalon.
13. Name, *in order of importance,* the organs in which animal heat is developed.
14. What variations of temperature are found in different parts of the body? Why?
15. Can a man live on an exclusively meat diet? Why?

MATERIA MEDICA AND THERAPEUTICS.

1. What remedies may be used to induce emesis? Give dose of each.
2. Name three mineral acids with therapeutic properties of each.
3. State uses and doses of salol, guaiacol, and heroin.
4. Give the source and physiological action of opium; name four preparations with adult dose of each.
5. Define alteratives; name five used in medicine with the therapeutic properties of each.
6. Compare the physiological action of aconite and digitalis; give adult dose of each.
7. Describe symptoms of ptomaine poisoning; outline the treatment.
8. Differentiate the effects of strychnine, nitroglycerin, and strophanthus on the arterial system.
9. Mention three vegetable and three mineral astringents with adult dose of each.
10. Specify the precautions to be used in administering chloroform; give reasons therefor.
11. Diagnosticate uremic poisoning; outline an eliminative treatment.
12. Explain the action and effects of phenacetin; give adult dose.

13. Prescribe in proper form for chronic bronchitis in an adult; explain the action of the ingredients used.
14. Enumerate the official preparations of arsenic; state the dose of each.
15. Give three examples of animal extracts with indications for the use of each.

CHEMISTRY.

1. (*a*) How does uric acid form in the system (*b*) Of what are gout stones principally composed? (*c*) What is the solubility of uric acid?
2. (*a*) State the origin of tartaric acid and other tartrates. (*b*) Give chemical formula of cream of tartar. (*c*) Rochelle salt.
3. (*a*) What are fats chemically? (*b*) What becomes of the fats ingested and what is the province of adipose in the body? (*c*) Under what condition does fat occur in the urine?
4. (*a*) What is nitroglycerin? (*b*) How is it used in medicine and what is its effect on the vascular system?
5. (*a*) What is chloral hydrate? (*b*) How does chloral act as a poison?
6. (*a*) What is the difference between ferrous and ferric salts? (*b*) Give examples by formulas.
7. (*a*) What is potassium permanganate? (*b*) Give formulas and its action as a disinfectant.
8. (*a*) Which are the two iodides of mercury? (*b*) Give formulas. (*c*) What is the difference in action of the "ous" and "ic" compounds of Hg?
9. (*a*) Define the term hardness as applied to a potable water? (*b*) What does the presence of an abnormal quantity of chlorides in a drinking water indicate?
10. Name three pigments normally present in human urine.
11. (*a*) Name three univalent elements. (*b*) Name a monobasic, a dibasic, and a tribasic acid radical.
12. (*a*) Give source, symbol, valency, and atomic weight of bromine. (*b*) What is acidum hydrobromicum dilutum (U. S. P.)?
13. (*a*) What is oxalic acid? (*b*) For what salt is it liable to be mistaken? (*c*) Give treatment for poisoning by oxalic acid.
14. (*a*) What are the principal constituents of cow's milk? (*b*) Give chemical explanation of the souring and curdling of milk.
15. Name the alkaloids of belladonna, aconite, nux vomica, and opium.

HISTOLOGY.

1. Give composition of human blood.
2. Mention different leucocytes and derivation of names.
3. What are thrombocytes?
4. Give structure of the mucous membrane of the stomach.
5. What cells line the larynx, trachea, bronchi, and bronchioles?

PATHOLOGY.

6. Give rôle of white blood-cells in infection.
7. What is hemolysis?
8. Define agglutination. How produced?
9. Define atelectasis; give causes and effects.
10. What will cause and what are the effects of exclusion of bile from the intestines?

BACTERIOLOGY.

11. Give chemical composition of bacteria.
12. What are proteid bodies? Name varieties and describe them.
13. What substances must be supplied to bacterial cells for their food?
14. Mention other bacterial functions besides disease production.
15. What are the fermentations of milk? Which are innocuous and which harmful? State effects of pasteurizing and boiling.

PRACTICE OF MEDICINE.

1. Describe bubonic plague.
2. Differentiate tonic and clonic spasms.
3. Describe the different stages of syphilis.
4. Differentiate cystic and renal hematuria.
5. Give the causes and symptoms of cholelithiasis.
6. Give the causes and symptoms of edema glottidis.
7. Give four physical signs present in consolidation of lung tissue.
8. How would you determine high blood pressure? What is its significance?
9. What, how much, and how often should a four months-old bottle-fed baby be fed?
10. Differentiate ataxia and aphasia, and give the location of the lesion in each.
11. Where is bronchial breathing heard normally? What does it indicate when heard elsewhere?
12. What is the significance of (1) epithelial; (2) granular; (3) fatty, and (4) waxy casts in the urine?
13. Describe the prodromal symptoms, giving the duration of each, in (1) scarlet fever; (2) measles, and (3) small-pox.
14. Give three causes for specific gravity of the urine (1) under 1010, and (2) over 1030, and the significance of each.
15. Describe vesicular, papular, and pustular inflammation of the skin and name a disease of which each is characteristic.

OBSTETRICS AND GYNECOLOGY.

1. What are the characteristics of the female pelvis and how does the male pelvis differ therefrom?
2. Describe the vulva (*a*) of a virgin, (*b*) of a multipara.
3. Describe (1) the process of fecundation, and (2) the uterine changes resultant.
4. Describe pelvimetry and name the five most important measurements.
5. Describe Walcher's posture and its uses.
6. What precaution as to the urine should be employed in the case of a pregnant woman?
7. Differentiate accidental hemorrhage, placenta prævia, postpartum hemorrhage.
8. Describe fully the treatment you would use in postpartum hemorrhage.
9. How should asphyxia neonatorum be managed?
10. Cause, preventive treatment, and curative treatment of ophthalmia neonatorum.
11. What causes puerperal infection? How may it be prevented?
12. How do you prepare a patient for an operation which is to involve both the abdominal surface and the vagina?
13. What are the causes of pelvic abscess? Outline treatment.
14. Describe the menopause and name the diseases common to that period of life.
15. Differentiate vaginitis and vaginismus and give treatment of the latter.

SURGERY.

1. Diagnosis and treatment of perforation of intestine in typhoid fever.
2. Give etiology, diagnosis, and treatment of empyema of the frontal sinus.
3. Give symptoms and treatment of ischiorectal abscess.
4. Treatment of compound fracture of tibia and fibula.
5. Describe tertiary syphilis of the pharynx.
6. Diagnosis of embolism of the mesentery.
7. Mention the causes of incontinence of urine.
8. What are the symptoms of cerebral compression?
9. Describe in detail lumbar puncture.
10. Diagnosis and treatment of papilloma of the bladder.
11. Give indications for drainage.
12. Mention the causes and symptoms of stricture of the rectum.
13. Give treatment of tubercular peritonitis.
14. Give diagnosis of lipoma of the neck.
15. Give diagnosis and treatment of aneurysm of the femoral artery.

HYGIENE.

1. Define hygiene.
2. What would you advise a person to do that fears pneumonia, rheumatism, nephritis, insomnia?
3. What is absolutely necessary for the maintenance of the healthy functions of the body?
4. What is antiseptic? What is meant by the term disinfection?
5. Name five disinfectants.
6. Why does a heated atmosphere charged with moisture render sunstroke liable?
7. State the time that quarantine should be imposed in (*a*) diphtheria; (*b*) smallpox.
8. What instructions should be given a nurse respecting the prevention of the spread of scarlet fever from the sick room?

MEDICAL JURISPRUDENCE.

9. State the difference between criminal and civil malpractice.
10. Name some of the violent causes of death.
11. Give in detail the condition which would warrant the induction of abortion by the practitioner.
12. Define the word "insanity."
13. Name the post-mortem signs, external and internal, of recent drowning.
14. When is induced abortion lawful and what are the conditions in which it is called for?
15. In a case of suspected infanticide what are the evidences of live birth?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

NEW JERSEY STATE BOARD OF MEDICAL EXAMINERS.

June 20 and 21, 1911.

ANATOMY.

1. See Cunningham's "Anatomy" (1909), pages 787 and 792; or Gray's "Anatomy" (1910), page 305.

2. MUSCULOSPIRAL NERVE. *Origin:* Posterior cord of the brachial plexus. *Branches:* Muscular, cutaneous, radial, and posterior interosseous. *Parts supplied:* Muscles of back of arm and forearm; and skin of back of arm, forearm, and hand.

3. *Five muscles of shoulder and arm:* Deltoid, subscapular, teres major, biceps, and triceps.

TRICEPS: The long, or middle, head arises from a depression on the axillary border of the scapula immediately below the glenoid cavity; the external head from the root of the great tuberosity on the posterior surface of the humerus, and the upper part of the musculospiral groove; the internal head from the posterior surface of shaft of humerus, below musculospiral groove, and the internal and external muscular septa. It is *inserted* into the back part of the upper surface of the olecranon process of the ulna. *Nerve supply:* Musculospiral. *Action:* Extends elbow and forearm; and extends and adducts the shoulder.

4. *Muscles attached to the great trochanter of the femur:* Gluteus medius, gluteus minimus, pyriformis, obturator internus, obturator externus, gemellus superior, gemellus inferior, and quadratus femoris.

5. *The superior mesenteric vein* returns the blood from the small intestine, cecum, ascending colon, and transverse colon.

6. *An anastomosis between portal and systemic veins:* The superior hemorrhoidal vein, a branch of the inferior mesenteric vein (portal), anastomoses with the middle hemorrhoidal vein, a branch of the internal iliac vein (systemic).

7. See Cunningham's "Anatomy" (1909, page 679; or Gray's "Anatomy" (1910), page 981.

8. *Nerves that supply the knee joints* are derived from the obturator, anterior crural, external popliteal, and internal popliteal.

9. *The pulmonary veins differ from the other veins:* (1) They carry arterial instead of venous blood; (2) they have no valves; (3) they are but little larger than the arteries which they accompany; and (4) they accompany the pulmonary arteries singly.

10. See Cunningham's "Anatomy" (1909), page 876; or Gray's "Anatomy" (1910), page 712.

11. See Cunningham's "Anatomy" (1909), page 900; or Gray's "Anatomy" (1910), page 743.

12. *Muscles which elevate the os hyoides and larynx:* Digastric, stylohyoid, mylohyoid, and geniohyoid.

Muscles which depress the os hyoides and larynx: Sternohyoid, sternothyroid, thyrohyoid, and omohyoid.

13. The upper fragment is flexed and supinated by the biceps and supinator brevis; the lower fragment is drawn down and pronated by the two pronators.

14. See Gray's "Anatomy" (1910), page 1277.

15. See Cunningham's "Anatomy" (1909), pages 912 and 914; or Gray's "Anatomy" (1910), page 786.

PHYSIOLOGY.

1. The formation of thrombin is necessary; this then reacts with the fibrinogen of the plasma and forms fibrin.

2. *Exercise* causes a decrease in the alkalinity of the blood; due, probably, to excessive production of sarcolactic acid in the muscles.

Digestion first causes an increase in the alkalinity of the blood, due to the secretion of hydrochloric acid; later, when the acid is absorbed, the alkalinity is diminished.

3. The normal amount of blood is said to be (roughly) about 1/13 of the body weight; so a man weighing 160 pounds should have about 12 to 13 pounds of blood.

Regeneration of blood after a hemorrhage: "If the bleeding does not go on to death the blood is restored by absorption from the tissues or from the food taken in; the first to be absorbed being the serum sanguinis, with the dissolved salts, and then the albumin. A longer time is required to form new red blood corpuscles. The regenerated blood is at first abnormally watery and poor in cells. As a result of the greater flow of lymph into the blood the number of the white blood corpuscles is greatly increased, and then their amount falls off; the red blood corpuscles again attain their usual number, and the composition of the blood gradually returns to the normal. We do not as yet know certainly how the restoration of the red blood corpuscles takes place. The most generally accepted view is that colorless corpuscles are being constantly formed in the lymph glands, in the spleen, the bone marrow, and in the liver, and a certain number of these colorless corpuscles change into the red disks."—(Tillmanns' *Surgery.*)

4. *Absorption* is the process by which the products of digestion are taken up by the circulatory system. The products of digestion find their way into the blood by two routes: (1) By the blood-vessels of the gastrointestinal tract, which unite to form the portal vein, and (2) by the lymph vessels of the small intestine, which converge to empty into the thoracic duct. The water, inorganic salts, proteids, and sugar go by way of the portal vein to the ascending vena cava; the fats go by way of the thoracic duct to the junction of the left subclavian and internal jugular veins.

The *process by which it is accomplished* is partly physical (osmosis and filtration), and is also due in part to selective action.

5. To be absorbed by the blood-vessels or lacteals the substances must be in a fluid state, and the more dilute the solution the more rapid the absorption. The absorbed matter must be rapidly removed and fresh blood supplied to the capillaries. Obstructed portal circulation delays absorption.

6. There are two theories as to the formation of lymph: (1) That it is formed from the blood plasma by the process of filtration, diffusion, and osmosis. (2) That, in addition to these, the endothelial cells of the capillaries exercise some influence.

Functions of lymph: To convey nutriment to tissues and cells of the body, and to gather up the waste material for elimination by the skin, lungs, and kidneys.

Lymph coagulates in the same manner as blood, but more slowly and feebly, owing to the less quantity of fibrinogen present in lymph. This property of coagulation is only found in the lymph in the vessels near the thoracic duct.

7. From the *ectoderm* are derived: The skin and its appendages (hair, nails), and glands (including the mammary glands); the nervous system (brain, spinal cord, ganglia, and nerves); the epithelial parts of the organs of special sense.

From the *mesoderm* are derived: The skeleton; connective tissues; muscles and bones; heart, blood-vessels, lymphatics, and spleen; the urinary and generative organs.

From the *entoderm* are derived: The epithelial lining of the alimentary canal and its glands; the epithelial lining of the respiratory tract, Eustachian tube, thyroid, and thymus.

8. The *Wolffian bodies* are the primitive sexual gland in the embryo; they later become the testicle in the male or the ovary in the female.

9. The corpus luteum is a scar on the surface of the ovary, where a vesicle has ruptured. It does not necessarily indicate pregnancy, though formerly it was supposed to be of some value in recognizing the former existence of this condition.

10. The special centers contained in the medulla are those for the following functions or actions: Respiration, salivary secretion, mastication, sucking, deglutition, speech production, facial expression; it also contains the cardiac and vasomotor centers.

11. *The function of the dura* is protection. It forms the internal periosteum of the skull, it forms three partitions for the support of the parts of the brain, it forms sinuses or venous channels for the return of the blood from the brain, and it forms sheaths for the nerves as they leave the skull. Of the *arachnoid*, lymph supply; of the *pia*, blood supply and nutrition.

12. The *function* of the *gray* matter in the encephalon is to receive and send out nervous impulses; the *white* matter conveys these impulses.

13. Muscles, secreting glands (and liver), digestive tract during digestion, and brain.

14. *Temperature of different parts of the body:* "The temperature of the skin at the middle of the upper arm is 35.4° C., while in the sole of the foot it is but 32.26° C. In the axilla it is about 37.1° C., although some observers have placed it as low as 36.25° C. and others as high as 37.5° C.; under the tongue, about 37.5° C.; and in the rectum about 38° C. The temperature of the liver, about 41.30° C. in the sheep, is regarded as the highest in the body, and higher here during digestion than in the intervals. The mean temperature of the blood may be stated as 30° C. The temperature of the muscles is increased in contraction 1° C. Mental exertion also increases the production of heat. After such exertion the temperature of the body has been found to be 0.3° C. higher than before."—(Raymond's *Physiology.*)

15. A man cannot live in health on an exclusive meat diet. A suitable diet requires carbohydrates and fat as well as protein material; meat has but little fat and practically no carbohydrate.

MATERIA MEDICA AND THERAPEUTICS.

1. *Emetics:* Ipecac, dose 15 grains; apomorphine hydrochloride, dose 1/10 grain; tartar emetic, dose ½ grain; zinc sulphate, dose 15 grains; copper sulphate, dose 4 grains; mustard and water, alum and water, yellow mercuric subsulphate, dose 2 to 4 grains.

2. THREE MINERAL ACIDS. Sulphuric acid, nitric acid, and hydrochloric acid. "They are all useful in fevers, if well diluted, hydrochloric being usually preferred, especially in typhoid. In atomic dyspepsia, acidity of the stomach, and locally in ulcerations of the throat, hydrochloric acid is best used. Nitric is the acid generally preferred as a caustic, its action being effectual and superficial. As such it is applied undiluted to phagedenic ulcers and sloughs, warty growths, and to the cavity of the womb in chronic inflammation thereof. Dilute nitric acid is used internally in oxaluria and lithemia, intermittent and remittent fevers, and aphonia of singers. Dilute nitrohydrochloric is more suitable in chronic hepatic disorders due to malaria; sulphuric in hemorrhages, diarrheas, colliquative sweating, and as a prophylactic against lead-poisoning. Dilute sulphuric acid is used as an acid drink in fevers and before meals in acidity of the stomach. It is very doubtful whether the latter has any special influence on the nerves or osseous systems." (Potter's *Materia Medica*, etc.)

3. SALOL. *Uses:* As a disinfectant, in inflammation of the mouth and pharynx, in cystitis, as an intestinal antiseptic in typhoid fever, in muscular rheumatism, in intestinal indigestion and fermentation, in cholera. *Dose:* gr. vijss.

GUAIACOL. *Uses:* In pulmonary tuberculosis, typhoid, diabetes mellitus. *Dose:* ♏viij.

HEROIN. *Uses:* In dyspnea, cough, whooping cough, asthma, and neuralgic affections. *Dose:* gr. 1/20 to 1/12.

4. OPIUM. *Source:* Papaver somniferum. *Physiological action:* It is analgesic, hypnotic, diaphoretic, narcotic, a respiratory and cardiac stimulant (later a depressant), it checks most secretions (not perspiration), it stimulates the brain, and contracts the pupil. *Four preparations and doses:* Extract of opium, gr. ½; tincture of opium, ♏viij; camphorated tincture of opium, 5ij; wine of opium, ♏viij.

5. *Alteratives* are remedies which alter the course of morbid conditions; their method of action is not known; it has been suggested that they promote metabolism.

Five examples: Arsenic, colchicum, phosphorus, guaiacum, and cod liver oil.

ARSENIC. *Physiological action:* Escharotic; irritant, tonic; increases cardiac action, respiratory power, intestinal secretions, and peristalsis; produces edema, itching, diarrhea, epigastric pain, irritable and feeble heart. *Therapeutic uses:* In stomach disorders, bronchial and pulmonary affections, diabetes, diarrhea, anemia, and chlorosis, chorea, malaria, and chronic skin diseases.

COLCHICUM. *Physiological action:* It causes salivation, irritation of the gastrointestinal tract, increased elimination of uric acid, and collapse; it is also a diuretic. *Therapeutic uses:* Chiefly for gout; also in neuralgia, headache, dyspepsia, and bronchitis in gouty people.

PHOSPHORUS acts locally as an irritant; internally it is a stimulant to the nervous system and also to the bone-forming cells, a tonic, a repairer of waste, a circulatory stimulant, and an aid to the formation of red blood corpuscles. It is partly oxidized into phosphorus acid or phosphoric acid by the oxygen in the red corpuscles. In large doses it increases the urea and other nitrogenous products, raises the body temperature, diminishes the glycogen of the liver, and may cause fatty degeneration.

GUAIACUM is a diaphoretic, expectorant, laxative, and gastrointestinal irritant. It is used for sore throats, tonsillitis, rheumatism, and constipation.

COD LIVER OIL is a demulcent and emollient, it is a tissue food. It is used in tuberculosis, rheumatism, strumous diseases, rickets, nervous diseases, and wasting diseases of childhood.

6. ACONITE. *Official preparation, with adult dose:* Fluid extract, ♏j; tincture, ♏x. *Medicinal uses:* For fevers, some inflammatory conditions, in high arterial tension, in nervous palpitation of the heart, and congestive dysmenorrhea; also externally for neuralgia, pruritis, herpes, chilblains, etc. *Therapeutic effects:* First stimulates and then paralyzes heart and also sensory nerves; lowers blood pressure; dilates peripheral blood-vessels; is a respiratory sedative; reduces body temperature; is a diuretic and dianhoretic.

DIGITALIS. *Physiological action:* It is a gastrointestinal irritant, it slows the rate of the heart, prolongs diastole, increases the force of the heart, it contracts the blood-vessels, and causes a rise in blood pressure; it also acts as a diuretic. *Therapeutic use:* Digitalis is indicated in diseases of the heart: (1) when the heart action is rapid and feeble, with low arterial tension; (2) in mitral lesions when compensation has begun to fail; (3) in nonvalvular cardiac affections; (4) in irritable heart, due to nerve exhaustion. Digitalis is contraindicated in diseases of the heart; (1) in aortic lesions when uncombined with mitral lesions; (2) when the heart action is strong, and arterial tension high. Digitalis is also a diuretic; and it is also used in some forms of nephritis, exophthalmic goiter, pneumonia, chronic bronchitis, etc. *Dose:* Fluidextract, ♏j; extract, gr. 1 5; infusion, 5ij; tincture, ♏xv.

7. See French's "Practice of Medicine" (1910), pages 996 and 997; or Osler's "Practice of Medicine" (1909), pages 381 and 385.

8. *Strychnine* is a vasoconstrictor, causes a rise of blood-pressure, and is a cardiac stimulant.

Nitroglycerin dilates the blood-vessels, causes flushing and rapid heart action, followed by fall of blood-pressure.

Strophanthus acts on the heart like digitalis (see QUESTION 6), but more promptly.

9. *Three vegetable astringents:* Gambir, dose gr. xv; tannic acid, dose gr. vij; nut-gall, dose of tincture 5j.

Three mineral astringents: Alum, dose gr. vij; copper sulphate, dose gr. 1/5; zinc sulphate, dose gr. j.

10. See Rose and Carless' "Surgery" (1908), page 1321; or Da Costa's "Surgery" (1908), page 1030.

11. See French's "Practice of Medicine" (1910), pages 906, 909, and 930; or Osler's "Practice of Medicine" (1909), pages 683, 685, and 702.

12. *Phenacetin* is an antipyretic and analgesic, it is a cardiac depressant, and has also been used in epilepsy. Dose, 7 grains.

13.

℞. Ammonii chloridi 5j
Ammonii carbonatis 5j
Ammonii bromidi 5j
Fluidextracti glycyrrhizæ 5iv.
Aquæ distillatæ q. s. ad 5vj. M.

Sig. A dessertspoonful every four hours.

The ammonium chloride stimulates the air passages; the ammonium carbonate stimulates the heart and respiration; the ammonium bromide allays the cough; the licorice hides the salty taste of the ammonium salts.

14. The official preparations of arsenic, with their doses, are: Arseni trioxidum, gr. 1/30; Liquor acidi arsenosi, ♏vij; Arseni iodidum, gr. 1/20; Sodii arsenas, gr. 1/6; Sodii arsenas exsiccatus, gr. 1/20; Liquor potassii arsenitis, ♏vij; Liquor sodii arsenatis, ♏v; Liquor arseni et hydrargyri iodidi, ♏vij.

15. THREE ANIMAL EXTRACTS:—(1) *Thyroid extract*, used in myxedema, goiter, sporadic cretinism, and arteriosclerosis. (2) *Suprarenal extract*, used in asthma, hay fever, Addison's disease, shock, as a local vasoconstrictor in minor surgery. (3) *Pituitary extract*, used in acromegaly.

CHEMISTRY.

1. (*a*) *Uric acid:* "In man uric acid has a twofold origin; one portion, coming from the breaking down of the nuclein-containing tissues or cell elements of the man's own body, and hence is of endogenous origin, while the other portion—usually the larger—is of exogenous origin, coming from the transformation of free and combined purin compounds present in the food." (Chittenden.)

(*b*) Gout stones are principally composed of: Sodium biurate, and potassium biurate; uric acid, sodium, potassium, calcium, and magnesium.

(*c*) Uric acid is insoluble in alcohol and ether; is slightly soluble in water; is soluble in sulphuric acid and hydrochloric acid.

2. (*a*) The tartrates exist in the juice of the grape, and are also obtained as a by-product in the manufacture of wine.

(*b*) *Cream of tartar:* $KHC_4H_4O_6$

(*c*) *Rochelle salt:* $KNaC_4H_4O_6$

3. (*a*) *Chemically*, fats are compounds of fatty acids with glycerin; they may be termed glycerides or glyceric ethers.

(*b*) The fats ingested finally exist in the small intestine as soaps and glycerin salts. These substances are absorbed by the columnar epithelial cells; they eventually pass into the lacteals, where they form an emulsion with the lymph and pass into the thoracic duct, and then into the blood. The fat droplets are then carried all over the body and are finally deposited in fatty cells in the adipose tissue.

"The *offices which fat subserves in the human body* are manifold: (1) It protects the underlying parts from injury as in the palm of the hand and the sole of the foot; (2) it serves as a lubricator, as in the sebaceous matter poured out upon the skin, which keeps it soft and pliable; (3) it acts as a nonconductor of heat, aiding in the retention within the body of the vital heat which would otherwise be lost so rapidly as to produce injurious results; (4) it serves as a reservoir when the supply of food is cut off or diminished: thus in wasting diseases the fat deposited in various parts of the body is absorbed, and contributes to its nutrition; (5) it is a source of energy and of heat through its oxidation, the final products of which are CO_2 and H_2O."—(Raymond's *Physiology.*)

(*c*) *Fat occurs in the urine*, in: Chyluria, pyonephrosis, fatty degeneration of kidney, chronic white kidney, acute phosphorus poisoning.

4. (*a*) Nitroglycerin is trinitroglycerol or glycerol trinitrate, $C_3H_5(NO_3)_3$.

(*b*) In medicine a 1 per cent. alcoholic solution is used, in doses of one minim. For effect on the vascular system, see MATERIA MEDICA, QUESTION 8.

5. (*a*) Chloral hydrate is trichloraldehyde and water; it has the constitution $C.Cl_3.CH(OH)_2$.

(*b*) Chloral acts as a poison by its direct action on the nerve centers; first in the gray matter of the center, then on the spinal cord, and medulla, and on the heart.

6. In the *ferrous* salts, the atom of iron is bivalent; in the *ferric* salts, the atom of iron is quadrivalent, and two of these atoms are united, thus forming a hexavalent group.

Ferrous oxide, FeO; Ferric oxide, Fe_2O_3; Ferrous chloride, $FeCl_2$; Ferric chloride, Fe_2Cl_6.

7. Potassium permanganate is a dark prismatic solid obtained by fusing a mixture of manganese dioxide, potassium hydroxide, and potassium chlorate. It has the formula $K_2Mn_2O_8$. It is a good oxidizing agent (each molecule having eight atoms of oxygen), and in this way acts as a disinfectant.

8. Mercurous iodide, Hg_2I_2; and mercuric iodide, HgI_2. The "ous" compounds of mercury make with KHO a black precipitate; the "ic" compounds of mercury make with KHO a yellow precipitate. In the case of the chlorides and iodides the "ic" compounds of mercury are more poisonous than the "ous" compounds.

9. (*a*) A water is said to be "hard" when it forms a curdy deposit with soap. (*b*) An abnormal quantity of chlorides denotes organic contamination, generally sewage.

10. *Three urinary pigments:* Urochrome, urobilin, and uroerythrin.

11. (*a*) *Three univalent elements:* Hydrogen, chlorine, and silver.

(*b*) HNO_3 is a monobasic acid, and its radical is NO_2.
H_2SO_4 is a dibasic acid, and its radical is SO_2.
H_3PO_4 is a tribasic acid, and its radical is PO.

12. (*a*) BROMIN. *Source:* Sea water and sea weeds. *Symbol:* Br. *Valency:* One. *Atomic weight:* 80.

(*b*) *Acidum hydrobromicum dilutum (U.S.P.)* is a liquid composed of 10 per cent. by weight of absolute hydrobromic acid, HBr, and about 90 per cent. of water.

13. (*a*) Oxalic acid is a dicarboxylic acid, with the formula COOH·COOH.

(*b*) It is liable to be mistaken for Epsom salt (magnesium sulphate).

(*c*) *Treatment for poisoning:* Magnesia or slaked lime suspended in a small quantity of water or mucilaginous liquid should be given as soon as possible. If vomiting does not occur and the symptoms of corrosion are not marked give an emetic. Do not use the stomach pump or tube.

14. (*a*) *Principal constituents of cow's milk:* Water, casein, albumin, fat, sugar (lactose), and salts.

(*b*) When milk is allowed to stand part of its lactose is changed into lactic acid; thus $C_{12}H_{22}O_{11} + H_2O = 4C_3H_6O_3$. This is due to the action of microorganisms. This lactic acid precipitates some of the caseinogen. The process is called *souring*.

The chief protein in milk is caseinogen; this, when acted upon by rennet, forms casein; the *curd* is casein and entangled fat.

15. ALKALOIDS. Of *belladonna*, atropine; of *aconite* aconitine; of *nux vomica*, strychnine and brucine; of *opium*, morphine, codeine, thebaine, narcotine, narceine, papaverine.

HISTOLOGY.

1. Human blood is composed of a liquid portion, the plasma, and solid bodies, the corpuscles. These latter are red corpuscles, white corpuscles, and platelets.

2. *Different leucocytes:* (1) Small mononuclear (having only one nucleus); (2) large mononuclear (having only one nucleus); (3) transitional (intermediate between mononuclear and polymorphonuclear); (4) polynuclear or polymorphonuclear (having more than one nucleus, or with various shaped nuclei); (5) eosinophile (readily taking the eosin stain).

3. Thrombocytes are blood platelets.

4. See Cunningham's "Anatomy" (1909), page 1059; or Gray's "Anatomy" (1910), page 1276.

5. The *larynx* is lined with stratified squamous and stratified ciliated epithelium; the *trachea*, with stratified ciliated; the *bronchi*, with stratified ciliated; and the *bronchioles*, with simple ciliated, simple columnar, and simple squamous cells.

PATHOLOGY.

6. See Rose and Carless' "Surgery" (1908), pages 11 and 32; or Da Costa's "Surgery" (1908), pages 78 and 127.

7. *Hemolysis* is destruction of the red blood corpuscles (by a specific antiserum or by poisons).

8. *Agglutination* is the loss of motility and the clumping in small masses of the microorganisms in a culture on the addition of a specific immune serum. It is supposed to be due to the development of agglutinins.

9. See French's "Practice of Medicine" (1910), page 700.

10. See French's "Practice of Medicine" (1910), pages 872 and 860; or Osler's "Practice of Medicine" (1909), page 547.

BACTERIOLOGY.

11. *Chemical composition of bacteria:* Water (about 80 to 88 per cent.); phosphoric acid, sulphur, potassium, chlorine, calcium, magnesium, iron, and silica; hemicellulose is often present; nuclein, hypoxanthin, guanin, and adenin are often present.—(From Jordan's *Bacteriology.*)

12. *Proteid bodies* are organic nitrogenous compounds containing carbon, oxygen, hydrogen, nitrogen, sulphur, and sometimes iron, of very complex constitution and whose molecule is undetermined.

Varieties: (1) *True or native albumins* (albumins proper, globulins, coagulating albumins, nucleoalbumins, histones, protamines).

(2) *Derived albumins or transformation products* (coagulated or modified albumins, acid and alkali albuminates, albumoses, peptones).

(3) *Proteids* (nucleoproteids, hemoglobins, glucoproteids, lecithoproteids).

(4) *Albumoids* (collogen, keratin, elastin, amyloid, spongin).

13. Most bacteria require proper temperature, generally at or near that of the body; oxygen is generally needed, those that cannot live without it being called aërobic and those that can grow without it anaërobic; nutriment of a proper kind, containing both organic and inorganic material (chiefly decomposable organic matter); a slight degree of moisture; a medium of slightly alkaline reaction; and rest. Individual bacteria may require modifications of the above essentials.

14. Besides diseases, bacteria may produce heat, light, colors, putrefaction, decay, fermentation, ptomaines, toxins, nitrites, odors, gases, acids, alkalies, and may liquefy gelatin.

15. The *fermentations of milk* are: Lactic, butyric, alcoholic. Of these the butyric is harmful, the others innocuous.

Pasteurizing milk kills the pathogenic germs and does not impair the nutritive qualities of the milk.

Boiling milk kills both the germs and their spores, and also impairs the digestibility of the milk.

PRACTICE OF MEDICINE.

1. See French's "Practice of Medicine" (1910), page 281; or Osler's "Practice of Medicine" (1909), page 239.

2. In *tonic spasms* the muscular contractions are continuous; in *clonic spasms* contractions and relaxations rapidly alternate.

3. See French's "Practice of Medicine" (1910), pages 428 and 433; or Osler's "Practice of Medicine" (1909), page 267.

4. In *renal* hematuria the blood and urine are intimately mixed, tube casts are apt to be present, and there may be renal colic or pain in the lumbar region. In *cystic* hematuria the blood and urine are not so well mixed, and pure blood is apt to be passed at the end of urination.

5. See French's "Practice of Medicine" (1910), page 868; or Osler's "Practice of Medicine" (1909), page 548.

6. See French's "Practice of Medicine" (1910), page 662; or Osler's "Practice of Medicine" (1909), page 598.

7. *Four physical signs of consolidation of lung tissue:* (1) Increased vocal fremitus; (2) dullness on percussion; (3) bronchial respiration with prolonged expiration; and (4) increased vocal resonance.

8. High blood pressure would be determined by the use of a sphygmomanometer. High blood pressure is found in: Chronic interstitial nephritis, arteriosclerosis, nervous excitement, uremia, myocarditis, lead poisoning, gout, cerebral hemorrhage, and sometimes in acute nephritis.

9. *For a fourteen-months-old bottle-fed baby.* "Five feedings in twenty-four hours are required, the interval between feedings being about four hours. The daily amount of food needed is from 40 to 50 ounces. Each feeding, therefore, should consist of from 8 to 10 ounces, of which four-fifths is milk and one-fifth some form of farinaceous food, thoroughly cooked, and then strained. . . . In preparing the food the milk and the gruel are simply mixed together while the latter is warm, and salt and a small quantity of cane sugar added to make it palatable."—(Holt.)

10. *Ataxia* may be defined as lack of coordination in muscular movements, so that the performance of certain acts becomes difficult or impossible. The lesion may be in the cortex of the cerebrum, pons, crura, corpora quadrigemina, cerebellum, or spinal cord.

Aphasia is the inability to express ideas by either speech or writing. It is caused by lesions of the cortical centers, and is not due to lesions of the peripheral nerves or of the organs concerned in speech or writing. The center for speech is in the third left frontal convolution.

11. *Bronchial breathing* is that which is heard normally over the trachea, larynx, or large bronchi. It is characterized by an entire absence of all vesicular quality; inspiration is high pitched and tubular; and expiration is longer, higher, and of greater intensity; there is an interval between the two sounds.

When heard elsewhere *bronchial breathing* may indicate consolidation of the lung, or a large cavity communicating with a bronchus; it is heard in phthisis, lobar pneumonia, and hemorrhagic infarction; it is also heard normally over the trachea and large bronchi.

12. *Waxy casts* occur especially in chronic parenchymatous nephritis. *Epithelial casts* occur especially in acute parenchymatous nephritis. *Granular casts* are especially common in chronic nephritis, but may occur in acute nephritis. *Fatty casts* occur chiefly in chronic parenchymatous nephritis.—(From Stevens' *Practice.*)

13. See French's "Practice of Medicine" (1910), pages 317, 326, and 301; or Osler's "Practice of Medicine" (1909), pages 132, 110, and 141.

14. (1) Urine may have *specific gravity under 1010* in: Diabetes insipidus, chronic interstitial nephritis, and hysteria.

(2) *Above 1030* in: Diabetes mellitus, fevers, diarrhea.

15. *Vesicles* are circumscribed elevated areas of the skin containing clear or opaque fluid, varying in size from a pinhead to a pea. *Example:* Herpes zoster.

Papules are circumscribed solid areas of elevation of the skin varying in size from a pinhead to a pea. *Example:* Comedo.

Pustules are circumscribed elevations of the skin containing pus and varying in size from a pinhead to a fingernail. *Example:* Furunculosis.

OBSTETRICS AND GYNECOLOGY.

1. The chief differences between the male and female pelvis are thus tabulated in Morris's *Anatomy:*

MALE.	FEMALE.
Bones heavier and rougher.	Bones more slender.
Ilia less vertical.	Ilia more vertical.
Iliac fossæ deeper.	Iliac fossæ shallower.
False pelvis relatively wider.	False pelvis relatively narrower.
True pelvis deeper.	True pelvis shallower.
True pelvis narrower.	True pelvis wider.
Inlet more heart-shaped.	Inlet more oval.
Symphysis deeper.	Symphysis shallower.
Tuberosities of ischia inflexed.	Tuberosities of ischia everted.
Pubic arch narrower and more pointed.	Pubic arch wider and more rounded.
Margins of ischiopubic rami more everted.	Margins of ischiopubic rami less everted.
Obturator foramen oval.	Obturator foramen triangular.
Sacrum narrower and more curved.	Sacrum wider and less curved.
Capacity of true pelvis less.	Capacity of true pelvis greater

2. In the *virgin:* The fourchet is present, the perineum is tense and deep, the labia are in apposition, and the hymen may be present.

In the *multipara:* The fourchet is missing, the perineum is relaxed and probably torn, the vulva is frequently patulous, there is no hymen, and there may be caruncule myrtiformes.

3. See Williams' "Obstetrics" (1909), pages 88, 94, and 164; or Hirst's "Obstetrics" (1909), pages 67 and 180.

4. See Williams' "Obstetrics" (1909), page 683; or Hirst's "Obstetrics" (1909), page 448.

5. See Williams' "Obstetrics" (1909), pages 11 and 738; or Hirst's "Obstetrics" (1909), page 528.

6. See Williams' "Obstetrics" (1909), page 201; or Hirst's "Obstetrics" (1909), pages 188 and 245.

7.

PLACENTA PRÆVIA.	ACCIDENTAL HEMORRHAGE.
Most commonly manifests itself after the sixth month of gestation, but may occur as early as the second month.	Most commonly occurs during the first stage of labor, but may occur at any time during the last three months of pregnancy.
The hemorrhage is abrupt, but painless.	The hemorrhage is sudden, and generally is attended with sharp pain.
There are generally repeated hemorrhages of increasing severity.	Hemorrhage persists until the uterine contents are evacuated or the patient perishes.
There is an edematous condition of the cervix and lower uterine segment, with marked pulsation.	Vaginal examination reveals no deviation from the condition normal to pregnancy.
Cervix is generally quite patulous, and within may be detected the placenta.	The cervix is perhaps (if labor be initiated) slightly patulous.
The placental bruit is situated low down.	The placental bruit is in normal position.

—(Dorland's *Obstetrics.*)

The above two occur *before labor;* postpartum hemorrhage occurs *after* labor; for the last see Williams' "Obstetrics" (1909), page 820; or Hirst's "Obstetrics" (1909), page 586.

8. See Williams' "Obstetrics" (1909), page 821; or Hirst's "Obstetrics" (1909), page 587.

9. See Williams' "Obstetrics" (1909), page 846; or Hirst's "Obstetrics" (1909), page 939.

10. OPHTHALMIA NEONATORUM. *Causes:* The gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloths, instruments, etc. *Symptoms:* Swollen eyelids, with copious purulent discharge; ulceration of the cornea may ensue. *Prophylaxis:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth. *Treatment:* Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

11. See Williams' "Obstetrics" (1909), pages 852 and 866; or Hirst's "Obstetrics" (1909), page 715.

12. See Williams' "Obstetrics" (1909), pages 371 and 445; or Hirst's "Obstetrics" (1909), pages 780 and 782.

13. PELVIC ABSCESS. *Etiology:* Pelvic cellulitis, rupture of tube (in ectopic gestation or pyosalpinx), pus from neighboring tissues, gonorrhea. *Treatment:* The abscess should be opened and drainage instituted, generally through the vagina. And see Williams' "Obstetrics" (1909), pages 863 and 888.

14. The *menopause* is the period when menstruation ceases. The symptoms of the menopause are referable to two stages: a stage of menstrual irregularity preceding the cessation of the menses, and a post-cessation stage of variable systemic disturbances. In normal or nearly normal cases the irregularities are not excessive: the systemic disturbances are slight. There is a period of unstable equilibrium. The woman may at times be unusually capricious and emotional; yet she passes through this physiological crisis with only a few minor disturbances. She may have the characteristic vasomotor flushes, perspiration, vertigo, somnolence, numbness, and faintness. The menstrual function ceases as it began, and other psychic disturbances are common in the abnormal cases, and may be exaggerated. The menstrual deviations vary in wide limits. The flow

may gradually decrease and come at lengthening intervals until it altogether ceases; it may occur at short intervals or become continuous; it may become so excessive as almost to amount to dangerous hemorrhage; or life may be jeopardized by a slow, continuous drain. There is an increased tendency to malignant disease of the uterus and breasts during this period. The excessive fear of this may prey injuriously on the mind of the woman.—(From Dudley's *Gynecology.*)

15. *Vaginitis* is a condition of inflammation of the vagina. It is characterized by redness, swelling, pain, heat, irritation, and increased secretion. There may be frequent and painful urination. *Treatment* consists in rest, cleanliness, douches, the application of soothing lotions, and removal of any cause; salines and anodynes are also indicated.

Vaginismus is a condition of painful and spasmodic contraction of the vaginal orifice, which renders coitus either painful or altogether impossible. The slightest touch causes painful spasms, and examination may be impossible without an anesthetic. Its *causes* are irritable hymen, ulcer, or fissure anywhere in the immediate vicinity, urethral caruncle, carunculæ myrtiformes, a long perineum with vaginal orifice placed too anteriorly. The *treatment* consists in removing the cause when possible, tonics and general constitutional treatment, dilatation of the vaginal orifice; local application of a 5 per cent. solution of cocaine will relieve the hyperesthesia and allow coitus. The condition is sometimes incurable.

SURGERY.

HYGIENE.

1. Hygiene is the science and art of all that tends to the maintenance and improvement of health, the prevention or shortening of the duration of diseases, and the prolongation of life.

2. The person should be advised to keep himself in as good health as possible, to shun the society of hypochondriacs, to lead an active and hygienic life. See also French's "Practice of Medicine" (1910), pages 153, 174, 223, 910, 915; or Osler's "Practice of Medicine" (1909), pages 165, 189, 219, 686.

For *insomnia:* The diet should be regulated, the evening meal should be light; exercise and laxatives may be required; the bedroom should be quiet, dark, well ventilated, and of moderate temperature; tea, coffee, and tobacco should be used sparingly, or avoided.

3. *For the maintenance of the healthy functions of the body:* Personal cleanliness, regulation of diet, avoidance of all excesses, suitable clothing, sufficient exercise in the open air, cleanly surroundings, plenty of suitable work.

4. *Antiseptic* is an agent which is destructive of microorganisms.

Disinfection is the process of destroying germs or inhibiting their activity.

5. *Five disinfectants:* Heat, steam, bichloride of mercury, carbolic acid, formaldehyde.

6. The extreme humidity prevents evaporation (which is one of the means of loss of body heat) so the body temperature is increased.

7. PERIOD OF QUARANTINE FOR: *Diphtheria:* till the patient is free from all signs of congestion or rhinitis, and continued bacteriological examination is persistently negative.

Smallpox: till all crusts or scabs have entirely disappeared.

8. See French's "Practice of Medicine" (1910), page 324; or Osler's "Practice of Medicine" (1909), page 138.

MEDICAL JURISPRUDENCE.

9. *Malpractice* is a failure on the part of a medical practitioner to use such skill, care, and judgment in the treatment of a patient as the law requires; and thereby the patient suffers damage. If due to negligence only, it is *civil* malpractice. But if done deliberately, or wrongfully, or if gross carelessness or neglect have been shown, or if some illegal operation (such as criminal abortion) be performed, it is *criminal malpractice.*

10. *Violent causes of death:* Wounds, burns and scalds, suffocation, strangulation, hanging, drowning, heat and cold, exposure, starvation, electricity, poisoning.

11. *Abortion is justifiable:* "(1) In pelvic deformity where there is sufficient space for a seven months' child to be delivered without injury. The object is twofold: (*a*) to save the child's life by obviating the necessity for craniotomy; (*b*) to spare the mother the dangers of craniotomy, cesarean section, symphyseotomy, or other operations that might be required if the pregnancy went to full term. (2) In cases where, in previous labors, the head of the child at full term has been prematurely ossified, or unusually large, or that labor has been difficult and dangerous, even though the pelvis were normal. The period of delivery need only be two or three weeks before 'term' in these cases. (3) In cases where the children of previous pregnancies have died *in utero* during the later weeks of gestation from disease (fatty, calcareous, or amyloid degeneration, etc.) of the placenta. (4) In conditions where the continuance of pregnancy seriously endangers the mother's life, such as: excessive vomiting; albuminuria; uremic convulsions, or paralysis; chorea; mania, organic disease of the heart, lungs, liver, blood-vessels, etc., threatening fatal disturbance of the respiration, circulation, and other disturbance of the respiration, circulation, and other vital functions; irreducible displacements of uterus; placenta prævia with hemorrhage; and in dangerous pressure upon neighboring organs from over-distention of uterus, due to dropsy of amnion, tumors, multiple pregnancy, etc."—(King's *Manual of Obstetrics.*)

12. According to Taylor, the term insanity is applied to those states of disordered mind in which a person loses the power of regulating his actions and conduct according to the ordinary rules of society. In all cases of real insanity the intellect is more or less affected.

13. In *death by drowning:* The surface is pallid, the face appears tranquil, the eyes and mouth being partly open. The skin often has the appearance known as gooseskin, and, if the body has lain upward of twelve hours in the water, that of the hands and the feet is sodden by imbibition. The most important external sign is the presence on the mouth and nostrils of a fine froth (possibly blood stained) composed of air, mucus, and the medium in which drowning took place; if the body remains three or four days in water the froth disappears. Exceptionally, fragments of weeds or other small objects may be found tightly grasped in the hands. On opening the thorax, the lungs, gray in color, with reddish staining, are seen to be very voluminous, a condition known as ballooning, partly due to infiltration of the lung tissue with some of the medium in which drowning took place, and partly to true edema. The lung substance is inelastic and pits on pressure. On section, fluid and froth resembling that found on the lips exude from the divided air passages. Minute subpleural hemorrhages are not infrequently present, and the pleural cavities may contain fluid. The stomach often contains water or other liquid which was involuntarily swallowed during attempts at respiration. Occasionally some of this fluid is forced by vital action into the intestines. With one exception, the remaining appearances are those met with after death from asphyxia. The exception is constituted by the blood, which is not only dark colored and fluid, as is usual after death from asphyxia, but is also diluted by the imbibition of water from the stomach and lungs.—(From Quain's *Dictionary of Medicine.*)

14. See QUESTION 11.

15. To constitute a "live birth" there must be (1) complete extrusion of the child from its mother's body, and (2) some certain sign of life. The latter would be established by one or more of the following: pulsation of the cord, beating of the child's heart, motions of the limbs, twitch-

ings of the muscles, wrinkling of the brows, puckering of the face, opening of the eyes, even if respiration does not take place.—(From Witthaus and Becker's *Medical Jurisprudence*, etc.)

BULLETIN OF APPROACHING EXAMINATIONS.

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 9
Arizona*	Ancil Martin, Phoenix	Phoenix	Oct. 2

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Radiological Diagnosis of Alterations of the Hypophysis.—M. Bertolotti gives his experiences with radiography of the hypophysis, preceding it with a statement and diagrams showing the normal radiographic picture of this portion of the skull. He calls this the profile of the normal cranium. It presents a constant line beginning in front with the frontal plate and ethmoid bones, in the supraorbital region, with two niches traversed by the fontal sinuses, forming a regular line along the base of the skull to the foramen magnum behind. This crosses the ethmosphenoidal region. Pathological variations of this profile are of the utmost importance in diagnosis. Radiography enables us to see how the hypophysis is modified in dystrophies and pathological processes, and to follow its evolution. The most interesting study refers to the transformations of the hypophysis and the sella tunica in the stages of evolution of acromegaly. We can see the enlargement of the sella, and the atrophy of the quadrilateral lamina of the sphenoid, which assumes a curvature with the concavity forward. This atrophy of the perpendicular lamina and curvature of the clinoid apophysis is the most important radiological appearance that can be observed in early acromegaly. In the second period of evolution of the disease we get decrease of the sphenoidal sinus. When the pterigoid tubercle is not flattened the optic chiama is not yet compressed. In the last stages we see that the pituitary gland has increased beyond the capacity of the sella and has destroyed the clinoid apophysis anterior and posterior. Now the visual field is always affected and the ophthalmoscopic and radiological pictures correspond. The author gives the pictures seen in tuberculosis of the hypophysis in tumors, etc.—*Rivista Critica di Clinica Médica.*

Medicolegal Notes.

Opinion as to Condition of Prosecutrix One Year after Offense Not Admissible in Trial for Rape.—In the course of a trial for rape a physician was permitted to testify to a physical examination of the prosecutrix made more than a year after the offense was alleged to have been committed. This witness was allowed, while stating that he was not an expert, nevertheless to give it as his opinion from this examination that the prosecutrix was not a virgin. His testimony to this effect was held, on appeal, to be a pure opinion and nothing else, and not given as the opinion of an expert, and to be clearly inadmissible. Pearson v. State, Mississippi Supreme Court, 53 So. 689.

In Suit for Professional Services Plaintiff Must Allege His Registration—In Texas He Cannot Prove Patient's Financial Condition.—A physician practising in the State of Texas without the license required by the Texas statutes cannot recover for his services. And a compliance with the requirements of the law regulating the practice of medicine and surgery having been made a condition precedent to the right to so practise, it is necessary for a physician suing for his services to allege in his petition and prove such compliance. If the plaintiff fails to allege in what State his services were performed the Texas statutes will govern. If they were performed in Texas the statutes would apply as a matter of course. If performed in some other State the presumption would obtain that the same statutes have been there enacted and are in force. In an action by a physician for the reasonable value of his professional services, on the question whether the plaintiff may show this value by proof that the defendant is wealthy, coupled with further proof of a custom among physicians to graduate their charges according to the financial condition of the patient, on which point there is a diversity of opinion among the courts, the Texas court held with the view that such testimony is not admissible. Swift v. Kelly, Texas Court of Civil Appeals, 133 S. W. 901.

Medical Expert's Qualification to Testify as to Electricity's Power to Kill.—In an action against a telephone company for the value of horses killed by electric shock there was no claim that the horses were not killed by electricity, but experts for the defendant contended that they were probably killed by lightning. A witness for the plaintiff, a physician and surgeon of many years' practice, whose qualifications as an expert witness with reference to experiments with electricity the court had examined, was allowed, after having stated what voltage was used in cases of electrocution, to answer the question whether it takes less voltage to kill a horse than it does a man. Anthony v. Telephone Co., Michigan Supreme Court, 130 N. W. 659.

Degree of Care Required by and Liability of Hospital Physicians.—In an action by a hospital patient for personal injuries alleged to have been caused by hospital physicians in treating a knee joint and thigh bone injured by a fall from a tree, there being no contract between the plaintiff and the defendants, they owed him no duty imposed on them because of their contract of employment with the hospital or in any way springing out of it. They owed him, however, the duty in the course of their employment not to do anything they either knew or ought to have known would injure him. Having with his assent undertaken to treat the plaintiff, the defendants were bound to exercise care in what they did and were liable if their failure to exercise ordinary care injured him. If they received no compensation whatever, that fact, while material upon the question of the care required of them, would not excuse them for their failure to exercise such care as the circumstances demanded. If they did not own or manage the hospital, or did not bring the plaintiff there or advise his coming, they were not chargeable for default in the hospital equipment or management, that is, because of any delay in setting the fracture due to the want of proper splints, the absence of a fracture bed, and the failure to use ether or an *x*-ray machine, if the hospital did not provide them. They were not responsible for the use of the facilities furnished by the hospital unless in the exercise of ordinary care they should have refused to employ in such a case such as the hospital furnished and by like care they could have procured more suitable appliances. They were not of course responsible for any default of other employees of the hospital in the management of the case before or after they ceased to have charge of it or of the default of each other. Burnham v. Stillings, New Hampshire Supreme Court, 79 Atl. 987.

Malicious Prosecution—Probable Cause—Belief That Plaintiff Is Practising Medicine Without Authority.—An action against a medical society for malicious prosecution in instituting a prosecution against the plaintiff for practising medicine within the State without legal authority

resulted in a judgment for the plaintiff, which was reversed on appeal. It appeared that the plaintiff was not authorized to practise medicine in the State: that he held himself out as a doctor and claimed to have produced a medicine which would cure glanders. He wrote to a person in a hospital suffering from that disease offering to cure him. He subsequently visited him in the hospital, examined him, and declared that he had glanders. He allowed himself to be addressed as a doctor, stated that he could cure the case, and left medicine with directions for its use. Under these circumstances it was held on appeal that there was probable cause for his prosecution. There was nothing to indicate that the defendant was actuated by malice, or that it had any desire to do otherwise than carry out one of the objects of its incorporation, which was to prevent persons practising medicine without being authorized to do so by the statutes of the State. It was unnecessary for the court to determine whether the plaintiff was actually engaged in the practice of medicine within the meaning of the statute; it was sufficient for the purpose of the appeal that there was at least probable cause for the defendant's belief that he was doing so.—Schmidt v. Medical Society of New York County, New York Appellate Division, 127 N. Y. Supp. 365.

Right to Recovery for Services Rendered to Patient Unconscious from Insanity.—Where a physician renders services to a patient, either on an express contract of employment or with the patient's consent, the law raises an implied promise on the part of the patient to pay him what the services are really worth. And where, in a proper case, a physician renders services to a person without his request or consent, or where one is injured by an accident rendering him unconscious, the law will imply a promise from him who received the benefit of the services to pay for them. Where, however, the plaintiff, a physician, rendered services to the defendant at the request of a physician in attendance, and the defendant had a regular physician, and it appeared that when the plaintiff was called the defendant was unconscious from insanity, but the unconsciousness lasted only two days, and the plaintiff continued the services after that, it was held that the plaintiff was not entitled to recover as on an implied contract.—Edson v. Hammond, New York Supreme Court, Appellate Division, 127 N. Y. Supp. 359.

Hypothetical Questions Must Be Warranted by Testimony—Opinion Based on Another Expert's Evidence Excluded.—In a murder case a physician was called as a witness for the defendant. He testified that he had examined the latter two or three days before, and that the lobes of the defendant's brain might be affected by a disease that he testified that he had, and that, if so, it would have a tendency to cause irascible mania and crime. In his opinion irascible mania and emotional insanity were practically interchangeable terms. He said that the prisoner must have been suffering from this condition at the date of the homicide, and in his judgment subject to what is known as impulsive insanity. Thereupon counsel for the defendant asked the physician a hypothetical question covering more than eight pages, apparently attempting to get up as facts to be assumed the testimony as the counsel understood it. The physician's answer was held properly excluded. Another physician was then called who had testified to defendant's diseased condition. Several questions were asked him, based in part on his understanding of what the first physician had testified, and these were also held properly excluded.—People v. Bowen, Michigan Supreme Court, 130 N. W. 706.

Qualification of Medical Expert—Professional Privilege.—In a rape case it was contended that neither of the two physicians who examined the complaining witness after the alleged rape qualified himself, because neither testified that he had ever had practical experience in a case of this kind. Both testified that they were active practitioners and had been such for a number of years. This was held to carry with it the fair inference that their testimony was based on actual experience. It was open to the accused to cross-examine them as to their practical knowledge. It was also claimed that they should not have been allowed to testify because their information came within the inhibition of the Wisconsin statute which provides that no physician shall be compelled to disclose information acquired while attending a patient professionally. The court did not decide whether this statute applies to criminal cases. But, assuming that it does, it must affirmatively appear that the information was acquired while the physician was attending the patient in his professional capacity and that it was necessary in order to enable the physician to prescribe.—Smith v. State, Wisconsin Supreme Court, 130 N. W. 525.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ended September 16, 1911:

	Cases	Deaths
Tuberculosis Pulmonalis	424	149
Diphtheria	130	12
Measles	79	5
Scarlet Fever	37	2
Smallpox	—	—
Varicella	7	—
Typhoid Fever	98	16
Whooping Cough	42	11
Cerebrospinal Meningitis	7	5
Malarial Fever	—	
Totals	824	200

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended September 15, 1911:

Places	Date	Cases	Deaths
CHOLERA			
Austria-Hungary: Fiume	Aug. 9–19	3	..
Ceylon: Colombo	July 23–29	1	2
India: Calcutta	July 16–29	..	20
Madras	Aug. 1–5	1	..
Indo-China: Saigon	July 10–Aug. 6	13	6
Java: Batavia	July 23–29	9	4

THE CLIMATIC AND HYGIENIC INFLUENCES OF FOREST GROWTH.*

BY JAMES M. ANDERS, M.D., LL.D.,

PHILADELPHIA, PA.

PROFESSOR OF MEDICINE AND CLINICAL MEDICINE IN THE MEDICO-CHIRURGICAL COLLEGE, PHILADELPHIA, PA.

IT is unreasonable to affirm, as some earlier writers have done, that desolation awaits the greater portion of the territory of the United States, on account of reckless denudation of the forests, and also that man's destructiveness and wastefulness of the national resources will only terminate with the direst unsought results to our civilization. Primitive man could not have found room for expansion without the preliminary removal of a portion of the forest growth, but there is clear and convincing historic evidence that wanton and thoughtless destruction of woods has too generally obtained during the past.

For the prevention of the evils of future unwarranted deforestation in this country we must look to the diffusion of greater knowledge on the subject and to the enlightened self-interest for which the American people are truly remarkable, and not trust to either state or national government alone, since these move with too slow a pace, as a rule. It would seem fitting, therefore, that this association should concern itself with those aspects of the question of forestry which bear more or less close relationship to meteorology, hygiene, and sanitary science. It is also clear that men of science, who, by virtue of their training, are peculiarly equipped to investigate the subject of the meteorological effects of the woodland, owe a debt in this respect to the general public—to others—yet it must be admitted that meteorologists have given less attention to this question in the past than it merits.

All progressive civilized nations aim to maintain and perfect an efficient system of forestry. While the United States has only recently begun to create a forest service, interest in the general subject is increasing at home, so that the present would appear to be an opportune season for making a brief survey of certain of its aspects, which possess more or less professional interest and importance. The diverse relations of forest growth to states of climate and the soil embrace numerous elements, many of which are not only complicating but also really conflicting; hence has arisen considerable divergence of opinion among the foremost authorities. Fortunately, the birth of forestry as a science has finally been witnessed in this country and important advances, the result of serious study, may be reasonably expected in the future.

*Read before the American Climatological Association, Montreal, Canada, June 13-14, 1911.

Formerly the conclusions of physicists respecting the meteorological influence of forests were in a great degree inferential, hence the conclusions reached by different writers were quite inharmonious. As Pinchot[1] pertinently remarks, it is a matter which is easily written and talked about without any thorough understanding of forestry itself. We are just beginning to approach the study of the question of the effect which forests exert upon climate in a proper manner, so as to give a clear conception, not only of the degree of their influence, but also the distance to which that influence reaches. It has been found that certain traditions concerning the influence exerted by forests upon climate have been fully confirmed by the results of recent scientific investigations, while others have been definitely shown to be unfounded.

Within the past two decades some knowledge has been gained by experiment or direct observation, and as the natural outcome of this work the balance of opinion at present writing favors the assumption that forests possess certain climatic effects of considerable practical significance. Unquestionably, the subject of the connection between forests and climate will require long and careful experiments and observations before a satisfactory solution shall have been reached.

It will be convenient to take up the various ways in which forests influence climatic factors seriatim: 1. Forests oppose resistance to the free passage of wind currents and moderate the extremes of temperature. Evidently trees are well adapted to check the movement of the air, since both branches and leaves, particularly in the case of bushy tree-tops, act as efficient barriers. The particles of air not checked by the first row of trees to the windward would have their force diminished and be promptly checked by the trees to the rear. Those of us who live in the Eastern States little realize to what extent wind breaks have been planted by farmers in the western part of our country to protect their crops and homes against the wind. In this manner considerable masses or even belts of trees, "by intercepting strong wind currents, not only afford shelter to man, the crops, and humbler vegetation generally to the leeward from the chilly blasts of winter but also the drying winds of summer, thus having the effect to modify extremes of temperature, rendering summer less sultry and winter less severe."[2]

The ameliorating influence of forests on the chilly spring and autumn winds is highly important to the agriculturist. It is well known that certain crops are slow in maturing, as in regions in which bleak winds prevail in unwooded districts, and it is undeniably true that, given similar soils, fruit grown in the city surpasses in quality and size that grown in the country—"a fact ascribable to the more effectual shelter in the former than in the latter locality." During the warm season the air of the woodland is

cooler than that outside. This fact is fully confirmed by the observations made abroad, more particularly in Bavaria and Württemberg, where it was shown that the highest temperature of every day in the year was lower by nearly 4° on the average, while the lowest temperature was higher by 2° in the forest. Says Pinchot:[3] "Prussian observations showed that for ten years the greatest heat of the day in July was, on an average, nearly 6° lower in the forest, and the greatest cold of the night in January nearly 3° less than outside." It is easily demonstrable that the air of the forest contains a somewhat higher standard of average humidity than that outside, and any increase in the amount of moisture in the air reduces the temperature, though the fall is not always proportional. M. Woeikoff[4] has called attention to the depressing effect of moisture upon the temperature, giving convincing illustrations from western Europe and Asia.

This influence may upon further investigation be found to be greater than the observations cited indicate, in our country at least, on account of the total absence of forests over immense areas of country and the extreme variability both as to temperature and humidity of our climate. It should be noted in passing that this action of forests upon the temperature is facilitated in a mechanical manner. The screen formed by the branches and foliar organs to a marked degree intercepts the solar rays, producing shade which has a delightful cooling effect by day, while it lessens the radiation of heat at night. The air coextensive with the shade being cooler than in the sun — these differences of temperature cause a slight motion in the air or draught. Von Pettenkofer's dictum, therefore, that shade in the open air always causes a slight draught, which acts as a kind of fan, is doubtless a correct one, and is due to differences in gravity of layers of air of unequal temperature.

Two additional ways in which forests affect the temperature of the air remain to be mentioned: First, the air is cooled by transpiration, or the evaporation of water from the leaves, and, secondly, the air below the covering formed by the forest leaves is kept cool in consequence of its absorption of the heat. The effect of the cooler air extends for some distance without the forest, since the falling colder air "flows off along the surface into the open country and causes local breezes" (Pinchot), while it is being replaced by a rising current of warmer air. It is well understood that these currents are reversed during the cold season, hence the forest is now warmer than the air at a distance. The opinion, therefore, that forests are natural equalizers of the temperature rests upon exact scientific premises.

Second, forests influence the atmospheric humidity in their vicinity. The effect exercised by growing forests upon the humidity of the surrounding air can justly claim a large share of importance. The explanation of the influence of the woodland upon atmospheric humidity includes certain well-known mechanical influences. In the first place, the vegetable canopy prevents, in a measure at least, the rays of the sun from reaching the earth and warming it, so as to facilitate evaporation from the soil. Again, forests, forming as they do a more or less perfect screen interposed between sky and earth, intercept to some extent the dews and lighter rains, "which are at once returned to the atmosphere by evaporation, a small portion of this moisture only reaching the earth." Ebermayer carefully computed evaporation from the soil of the forests as rather more than one-third as great as from the open soil. The amount of moisture arising from the soil of the forests is also potently influenced by the presence or absence of leaf mold. Ebermayer found as the result of experimental observation that evaporation from forest soil without a layer of mold was 47 per cent. of that from soil in the open, while with a layer of mold it was less than half as much, or 22 per cent. These facts have been advanced as powerful reasons for preserving forests at the headwaters of streams, more particularly in mountainous districts, since it has been definitely shown that the effect of the forest in preventing evaporation becomes greater with increasing altitude.

My own experiments with the view to determining the amount of aqueous vapor evaporated from known areas of leaf surface and land surface under similar conditions for the sake of comparison gave the uniform result that the evaporation from the former is greatly in excess of mere surface evaporation. From facts of observation it is reasonably certain that transpiration is one of the principal factors in connection with the influence exerted by forests upon atmospheric humidity.

While a leading effect of wooded districts is to preserve the moisture of the soil without favoring excessive humidity of the superficial strata by impeding evaporation from their soil, the trees are always supplied with an abundance of moisture for transpiration, owing to the power which they have to attract moisture from every direction as well as to retain the rainfall in their network of smaller rootlets, to be in due season absorbed by the myriads of root hairs. Much of the moisture drunk up by the roots of trees is returned to the atmosphere by the process of transpiration, which is practically uniform during clear, warm weather. For example, experiments long since conducted by the writer showed that "more than one and a quarter ounces of watery vapor per square foot of leaf surface for twelve diurnal hours" was lost by the average tree.

On comparing the mean transpiration from one square foot of leaf surface with an equal area of soil under like circumstances of exposure, it was found that the result obtained was 6 to 1 in favor of the latter. If it were definitely known how many times greater the leaf surface of a forest is than the land on which it is situated, it might with ease be computed what is the relative evaporation rate from a forest as compared with an equal area of open country. From certain personal observations it is safe to assume that the leaf surface of a wooded district is, as a rule, more than six times greater than that of the ground on which it stands, hence it follows that transpiration from the forests must exceed the evaporation from that of an equal area of open soil. It was also shown experimentally that the humbler specimens of vegetation exercise an effect in the same direction. It would seem to me to be entirely warrantable to draw the *a priori* conclusion that wherever a fair proportion of woodland exists, properly distributed, a considerable influence must be exerted thereby upon the hydrometeorology of the region. On the other hand, during the cold season forest vegetation obviously distills into the atmosphere little or no moisture, but their deeper underlying root terminals, after a spongelike fashion, hold considerable moisture in the soil, hence the earth in their vicinity is more humid than elsewhere in winter.

In view of the foregoing facts it is also clear that if the forest air be cooler its relative humidity must be greater than that of the air outside. It has been shown by actual observation that the average humidity of the forest air is from 3 to 10 per cent. greater than that of the outer air. These differences are exaggerated with the altitude above the sea level and the density of the forest vegetation. It is not pretended to claim that the increased humidity of the forest air as compared with that of the air at a distance is due alone to the function of transpiration, but this difference is also accounted for in part at least in other ways previously explained. On the other hand, what is definitely known concerning transpiration with respect to its almost inconceivable rate and uniformity during clear weather throughout the warm season may be restated, as showing that it is a factor not to be omitted from consideration. Moreover, the effects of this function are, for reasons before stated, manifested to a less marked degree within the forest area than upon the immediately surrounding atmosphere.

The question, however, to what distance the influence of the woodland upon the relative humidity of the air extends beyond its own borders is still imperfectly understood. In this connection Pinchot points out that a system introduced in Austria is expected to give a clearer idea; it consists of lines of stations beginning in the center of a large forest and extending step by step into the open country beyond.

The physiological function transpiration from facts of observation produces an appreciable effect upon the meteorological element humidity, but, more than this, it maintains a more nearly uniform degree of atmospheric moisture than is to be found at a distance. It is not too much to claim that forests are natural equalizers of both temperature and atmospheric humidity.

3. Forests produce ozone. One of the beneficial effects of forests is attributable to their energy in developing ozone. My own observations, which have been detailed elsewhere, showed that ozone is generated by odorous foliage and all of the flowering species, more particularly by scented flowers.[5] According to my researches the exhalations from the conifera were particularly energetic in the production of ozone—a fact that affords "an opportunity of entering a seasonable plea for the more careful preservation and cultivation of American pines."[6]

In this connection it is to be recollected that during the winter season forests do not develop any of this substance. This conclusion is measurably confirmed by the results of the careful researches of Nicholson, who found ozone more abundant in pine forests than in the open country in summer, and less abundant in winter. The writer found that the ozone-generating function is to a less degree under the control of the temperature than the action of the direct rays of the sun, so that outdoor vegetation, if we except periods of stormy weather, is constantly active in aiding to maintain the needful supply of atmospheric ozone.

Ozone through its power to combine chemically with pernicious organic impurities probably constitutes nature's principal means of purifying our atmosphere. It was the late Prof. Max von Pettenkofer who said: "It is the constant purifier of the atmosphere from all organic matter which passes into it and might accumulate. The air would have been long ago filled with the vapors of decomposition if it were not for ozone, which oxidizes all that is oxidizable if only time be allowed for it, and not too much is expected at once." It is interesting to note the intimate association of certain of the principal plant functions with the laws of hygiene, or, in other words, to behold important sanitary influences residing in mysterious physiological functions of living vegetation.

The sanitary influences of forest growth are principally dependent upon the two physiological functions already discussed, namely, transpiration and ozonification, but these do not extend to any great distance beyond the borders of the woodland, or, in other words, their effects are chiefly local in character; it follows that careful attention should be paid to the distribution and topographic arrangement of our forest growth.

Without detaining my hearers with a description of special places the value of forests and particularly pine groves to the consumptive will be readily conceded. There are no facts to oppose the practice of sending cases of laryngeal tuberculosis to the pine forests, where patients can obtain the superior benefits arising from a highly ozonized and terebinthinated atmosphere, if these resorts afford ordinary home comforts.

In view of the known effects of the plant functions, transpiration and the generation of ozone, there can no longer be any question as to the sanitary importance to a municipality of public squares provided that they be filled with appropriate growing vegetation. While this subject is not germane to the present discussion, it is desired to point out in passing that city parks, if properly supervised, possess hygienic advantages apart from their value as mere breathing spaces.

On reviewing briefly the foregoing discussion of the climatic and sanitary relations of forests we find them thrice illustrious: (a) as modifiers of extremes of temperature, particularly the diurnal range, which is of greater sanitary importance than seasonal variations, while at the same time rendering summer less sultry and winter less severe; (b) as natural atomizers of aqueous vapors, whereby they tend to maintain an unvarying degree of atmospheric humidity in their vicinity, and (c) as natural producers of ozone, which removes the organic impurities from the atmosphere by oxidation.

I have endeavored in the foregoing discussion to state only well-established facts, and if I have succeeded in so doing then the few conclusions which I have drawn from them are, it is hoped, logically sound. Lastly, there is a fair prospect that more definite beneficial effects will be attributed to forest growth as the result of systematic investigations now in progress and in contemplation.

THE PREVALENCE OF INTESTINAL PARASITES AMONG IMMIGRANTS.

By HERBERT M. MANNING, M.D.

PASSED ASSISTANT SURGEON, U. S. PUBLIC HEALTH AND MARINE HOSPITAL SERVICE.

While stationed at the U. S. Immigration Station, Ellis Island, New York, I was able to make a microscopic examination of the feces of 412 immigrants to determine the presence of intestinal parasites. These examinations were made during the period from October 8, 1910, to February 9, 1911. The immigrants examined were some of those sent to the immigration station hospital for medical observation and treatment, but none were admitted for causes that might influence the rate of prevalence of intesinal parasites except as will be mentioned below.

The feces were sent to the laboratory in a wide-mouth 3-ounce bottle and were examined by mixing a small amount with a drop of water on a slide, covering with a cover glass, and placing under both the high and low powers (Zeiss AA and CC). Generally at least two slides were examined, but as this was done in the course of other work I was unable to devote the time necessary to examine a greater number of slides or to use other special methods of examination such as sedimentation, etc.

The immigrants examined (Table 1) were from the following countries: Algiers 3, Austria-Hungary 66, Belgium 1, British West Indies 2, Canada 1, France 2, Germany 7, Great Britain and Ireland 7, Greece 43, Holland 1, Italy 108, Persia 2, Portugal 2, Roumania 3, Russia 105, Spain 2, Sweden 3, Switzerland 1, and Turkey 53.

The number of infections found with the following parasites were: whip worms (*Trichuris trichiura*), 91; eel worms, (*Ascaris lumbricoides*), 118; pin worms, (*Oxyuris vermicularis*), 1; old world hook worms, (*Ankylostoma duodenale*), 1; Cochin China worms, (*Strongyloides stercoralis*), 2; and tape worms, 7. Of the latter 1 was the *Dibothriocephalus latus*, 2 were *Tænia saginata*, and in the 4 others the oconospheres of *Tænia* were found in the stools, but no segments or worms were obtained so that the species were not determined, but they were in all probability *Tænia saginata*.

Forty-six were infected with both the *Trichuris trichiura* and *Ascaris lumbricoides*, 2 were infected with both *Tænia* and *Trichuris trichiura*, 1 with *Tænia* and *Ascaris lumbricoides*, and 1 with *Dibothriocephalus latus* and *Trichuria trichiura*. One was infected with *Trichuris trichiura, Ascaris lumbricoides*, and *Strongyloides stercoralis;* and 1 with *Ankylostoma duodenale, Oxyuris vermicularis*, and *Trichuris trichiura*.

Sixty-six from Austria-Hungary (Table 2) were examined, of whom 16, or 24.2 per cent., were infected with 1 or more intestinal worms. Of the 35 males, 8, or 22.8 per cent., and of the 31 females, 8, or 25.8 per cent., were infected. Twelve, or 18.1 per cent., were infected with *Trichuris trichiura*. Seven, or 20 per cent. of the males and 5, or 16.1 per cent., of the females harbored this parasite. Ten, or 15.1 per cent., were infected with the *Ascaris lumbricoides*. Four, or 11.4 per cent., of the males and 6, or 24 per cent., of the females were infected with this worm. Three males and three females were infected with both the above parasites.

Dividing these immigrants into four age periods after the manner of Stiles and Garrison in "A Statistical Study of the Prevalence of Intestinal Worms in Man," (Hygienic Laboratory Bulletin No. 28), the 15 examined who were under fifteen

TABLE II.

Austria-Hungary.

Age	Number examined			Number infected			Whipworms			Eelworms			Number infections			Infections per Hundred
	Male	Fem'le	Total	Male	Fem'le	Total	Male	Fem'le	Total	Male	Fem'le	Total	Male	Fem'le	Total	
0–14	6	9	15	1	4	5	1	3	4	1	3	4	2	6	8	53.3
15–30	19	19	38	5	4	9	4	2	6	3	3	6	7	5	12	31.5
31–50	10	3	13	2	..	2	2	..	2	..	..	..	2	..	2	15.3
51+	..	..	..	..	..	..	..	..	..	..	..	..	..	..	..	...
Total	35	31	66	8	8	16	7	5	12	4	6	10	11	11	22	33.3
Per cent	..	..	..	22.8	25.8	24.2	20.0	16.1	18.1	11.4	24.0	15.1	31.4	35.4	33.3	...

years of age had 8 infections, or 53.3 infections per 100 persons; the 38 between 15 and 30 years of age had 12 infections, or 31.5 per 100; and the 13 between 31 and 50 years had 2 infections, or 15.3 per 100. None of the immigrants from Austria-Hungary were 51 years old or over. The total number of infections for the 66 examined was 22, giving the rate of 33.3 per 100 persons. For the 35 males examined there were 11 infections, or 31.4 per 100, and for the 31 females, 8 infections, or 35.4 per 100.

Among those from Austria-Hungary the whip worm was the most prevalent parasite. This was also more prevalent among the males than among the females, while the *Ascaris* occurred more frequently among the females. The total number of infections per 100 is greater for the females than for the males. Also the first 15 years of life show the heaviest infection, which gradually decreases with age.

Forty-three immigrants from Greece (Table 3) were examined, of whom 13, or 30.2 per cent., were infected. Thirty-seven were males with 10, or 27 per cent., infected, and 6 were females with 3, or 50 per cent., infected. Nine, or 20.9 per cent., were infected with the *Trichuris trichiura*. Eight males, or 21.6 per cent., and 1 female, or 16.6 per cent., harbored this parasite. Eight, or 18.6 per cent., were infected with the *Ascaris lumbricoides*, of whom 6 were males and 2 were females, giving the rates of 16.2 and 33.3 per cent. The eggs of a tape worm were found in the feces of a female. This was probably *Tænia saginata*, but as no segments were obtained, no diagnosis could be made. The rate for *Tænia* among the Greeks was 2.3 per cent. Four males and 1 female were infected with both the whip worm and the eel worm.

were 13 infections, or 41.9 per 100; among the 7 between 31 and 50 years there was 1 infection, or 14.2 per 100; and among the 2 who were over 51 years of age there were not any infections. Among the 43 Greeks examined there were 18 infections, or 41.8 per 100. Among the 37 males there were 14 infections, or 37.8 per 100, and among the 6 females there were 4 infections, or 66.6 per 100.

Among the Greeks the *Trichuris trichiura* was the most frequent intestinal parasite and was also the most frequent in the male. The *Ascaris lumbricoides* occurred more frequently among the females. The rate of total infections was greater for the female than the male. The Greeks also show

One boy was found infected with the *Ankylostoma duodenale.* His anemic condition caused him to be suspected of being infected with this parasite so that it was not a case that was discovered purely by accident. If we consider this as being counterbalanced by the lack of thorough search for light infections, the rate of occurrence of this worm among the Italians would be .925 per 100. This boy was also infected with the *Oxyuris vermicularis,* this parasite being recovered along with the hook worms after the administration of thymol. The *Trichuris trichiura* was also present in this case. Fourteen were infected with both the *Trichuris trichiura* and the *Ascaris lumbricoides,* and

the heaviest infection in early life, which lessens with age.

Fifty-seven, or 52.7 per cent., of the 108 Italians examined (Table 4), 40, or 55.5 per cent., of the 72 males, and 17, or 47.2 per cent., of the 36 females, were infected with intestinal parasites. Twenty-four, or 22.2 per cent., were infected with the *Trichuris trichiura,* and of these 19 were males and 5 were females, giving the rates respectively 26.3 and 13.8 per 100. Forty-seven were infected with the *Ascaris lumbricoides,* of whom 32 were males and 15 females, giving a rate of occurrence 2459—Medical Rec., Sept.1—V A N L I E W for all Italians of 43.5, for the males 44.4 and for the females 41.6 per 100.

of these 11 were males and 3 were females.

Among the 25 Italians under 15 years of age there were 21 infections, or 84 per 100, among the 58 between 15 and 30 years of age there were 36, or 62 per 100, among the 21 between 31 and 50 years there were 12, or 57.1 per 100, and among the 4 51 years of age or over there were 4 infections. This shows that the rate of infection is heaviest in early life and decreases with age, except that the rate for those over 51 exceeds that for any other age period, but this may be purely accidental on account of the small number examined.

Among all the Italians examined there were 73 infections, or 67.5 per 100, among the males 53 infections, or 73.6 per 100, and among the females

20, or 55.5 per 100. The *Ascaris lumbricoides* is the most frequent intestinal parasite among the Italians, and it is more prevalent among the males than the females. The males are also more frequently infected with the *Trichuris trichiura* than the females. The total number of all infections per 100 is greater among the males than the females.

One hundred and five immigrants from Russia (Table 5) were examined and 53, or 50.4 per cent., were infected. Of the 65 males 35, or 53.8 per cent., and of the 40 females 18, or 45 per cent., were infected. Thirty-four were found infected with the *Trichuris trichiura* of whom 24 were males and 10 were females. The rate of occurrence of this worm is 32.3 per 100 for all from Russia, 36.9 per 100 for the males and 25 per 100 for the females.

Thirty-six were found infected with *Ascaris lumbricoides* of whom 23 were males and 13 females, the rate for all Russians being 34.2 per 100, for the males 35.3, and for the females 32.5. One male was found infected with *Strongyloides stercoralis*, and 1 female with *Dibothriocephalus latus*, giving the rate of prevalence of these worms as .926 per 100. Eleven males and 5 females were infected with both the *Trichuris trichiura* and *Ascaris lumbricoides*. One female was infected with both the *Trichuris trichiura* and *Dibothriocephalus latus*, and 1 male with the *Trichuris trichiura*, *Ascaris lumbricoides*, and *Strongyloides stercoralis*.

Among 20 who were under 15 years of age there were 18 infections, or 90 per 100; among the 70 between 15 and 30 years of age there were 45 infections, or 64.2 per 100, and among the 15 between 31 and 50 years there were 9, or 60 per 100. There were 72 infections among all the Russians examined, 48 among the males and 24 among the females, giving the rates respectively of 67.6 per 100 for all Russians, 73.8 for the males and 60 for the females.

Among the immigrants from that country the *Ascaris lumbricoides* was the most frequent intestinal parasite and both this worm and the whip worm occurred more frequently among the males than among the females. The rate of total infections was greater among the males than among the females, and also the rate of infection was heaviest in early life and decreased with age.

Of the 53 immigrants from Turkey (Table 6) examined, 20, or 37.7 per cent., were found infected. Of the 45 males 17, or 37.7 per cent., and of the 8 females 3, or 37.5 per cent., were infected. Seven males and 1 female were infected with the *Trichuris trichiura*, making the rate of the occurrence of this worm among those from Turkey as 15 per 100, among the males 15.5, and among the females 12.5 per 100. Fourteen, or 28.3 per cent., were infected with *Ascaris lumbricoides* of these 13 were males and 1 female, the rates for the two sexes being respectively 28.8 and 12.5 per 100.

The eggs of *Tænia* were found in the stools of 3 males and 2 females. In the case of 2 males the tape worms were determined as *Tænia saginata* from the segments also present. In the other 3 cases the species were not determined. The rate of infection with *Tænia* was 9.4 per 100, for the males 6.6, and for the females 25 per 100. The following double infections occurred: 4 males with both *Trichuris trichiura* and *Ascaris lumbricoides*, 1 male and 1 female with *Tænia* and *Trichuris trichiura*, and 1 male with *Tænia* and *Ascaris lumbricoides*.

Among the 7 under 15 years of age there were 3 infections, or 42.8 per 100. Among the 39 between 15 and 30 years there were 19 infections, or 48.7 per 100. Among the 7 between 31 and 50 years there were 5 infections, or 71.4 per 100. Among the total of 53 examined there were 27 infections, or 50.9 per 100, among the 45 males 23 infections, or 57.1 per 100, and among the 8 females 4 infections, or 50 per 100. Among those from Turkey the *Ascaris* was the most frequent intestinal parasite, and both this worm and the whip worm occurred more frequently among the males than among the females. The infections with *Tænia* was more frequent among the females. The rate of all infections with intestinal parasites seemed to increase with age, and the rate of infection was slightly greater for the males than for the females.

The following immigrants (Table 1) were also examined but the number was hardly great enough to draw any conclusions as to the prevalence of intestinal parasites among any of these nationalities. There were 3 males from Algiers of whom none were infected; 1 female from Belgium, who was found infected with *Ascaris lumbricoides;* 2 males from the British West Indies, 1 of whom was infected with the *Strongyloides stercoralis;* 1 male from Canada who was found free from infection; 1 male and 1 female from France, both of whom harbored the *Trichuris trichiura;* 5 males and 2 females from Germany of whom 1 male harbored the *Trichuris trichiura,* and 1 male the *Ascaris lumbricoides;* 6 males and 1 female from Great Britain and Ireland; 1 female from Holland; 2 males from Persia; 2 males from Portugal; 1 male and 2 females from Roumania, and 2 male from Spain, all of whom were found free from intestinal worms, three males from Sweden, 1 of whom was infected with both the *Ascaris lumbricoides* and *Trichuris trichiura*, and 1 female from Switzerland who was found free from infection.

Of the 412 immigrants of all nationalities (Tables 1 and 7) examined 166, or 40.2 per cent., were infected with one or more intestinal worms. Of the 282 males 115, or 40.7 per cent., and of the 130 females 51, or 38.4 per cent., were infected. Ninety-one, or 22 per cent., were infected with *Trichuris trichiura*, of whom 68 were males and 23 females, giving the rates of 24.1 and 17.6 per

TABLE VII (*Continued*)

PINWORMS			STRONGYLOIDLS			ANKYL. DUODENALE			TAPEWORMS			NUMBER INFECTIONS			Infections per Hundred

....	....	....	....	....	....	....	....	....	....	2	2	23	7	30	42.8
....	....	....	....	....	....	....	....	....	....	....	....	4	....	4	57.1
1	....	1	2	....	2	1	....	1	3	4	7	155	65	220	53.39
....	....	.24	....	....	.48	....	....	.24	1.06	3.07	1.69	54.9	50.0	53.39	....

100 respectively. The rate of infection with this parasite was highest among those from Russia; the rates for the different countries were 18.1 per 100 for Austria-Hungary, Greece 20.9, Italy 22.2, Russia 32.3, and Turkey 15 per 100. It was the most frequent parasite found among those from Austria-Hungary and Greece, and among these the males were more frequently infected than the females.

The *Ascaris lumbricoides* was present 118 times, or 28.6 per 100. Among the males 80, or 28.3 per cent., and among the females 38, or 29.2 per cent., were infected with this worm. The rates for the different nationalities were: Austria-Hungary 15.1, Greece 18.6, Italy 43.5, Russia 34.2, and Turkey 28.3 per 100. Italy showed the highest rate for this parasite. This is the most frequent parasite found and occurs more frequently among the females than the males, although Italy, Russia, and Turkey show a higher rate for the males.

Only 1 infection with the *Oxyuris vermicularis* was found, but no doubt the reason for not finding it more frequently was due to the rarity with which the eggs are found in the feces.

Two cases of infection with the *Strongyloides stercoralis* were found, 1 in an immigrant from the British West Indies and 1 from Russia. The rate of occurrence of this parasite for all immigrants examined was 0.48 per 100. Both of these cases were in males, and in the case from the West Indies his anemic condition suggested the suspicion of hook worm infection, but after repeated examination of several fresh stools, no ova were found, but numerous larvæ of the Cochin China worm.

The Italian boy infected with the *Ankylostoma duodenale* was the only case of hook worms found. The rate of occurrence of this parasite among all the immigrants examined is .24 per 100.

Seven infections with tape worms were found, 1 a case of infection with the *Dibothriocephalus latus* in a Russian woman, 3 males and 2 females among those from Turkey, and 1 female child among the Greeks. Two of those among the Turkish men were *Tænia saginata* and in the case of the 4 others the species were not determined. The rate of prevalence of the *Dibothriocephalus latus* among the Russians was .95 per 100, the rate of *Tænia* among the Greeks being 2.3, and among the Turks 9.4 per 100.

Among the 76 immigrants under 15 years of age there were 58 infections, or 76.6 per 100. Among the 259 between 15 and 31 years there were 128 infections, or 49.4 per 100. Among the 70 between 31 and 50 years there were 30 infections, or 42.8 per 100. Among the 7 over 51 years of age there were 4 infections, or 57.1 per 100. This shows that among all the immigrants examined the heaviest infection occurred in early life and tends to diminish with age. The rise in the case of those over 51 years may be due to accident on account of the small number examined.

Among the 412 immigrants there were 220 infections, giving the rate of prevalence of intestinal parasites as 53.39 per 100. Among the 282 males there were 155 infections, or 54.96 per 100, and among the 130 females there were 65 infections, or 50 per 100, showing that intestinal worms are slightly more frequent among the males than among the females.

According to the annual report of the Commissioner-General of Immigration for the fiscal year 1909-10 of the 1,041,570 immigrants coming to the United States during that year, 278,737 came from Austria-Hungary; 25,888 from Greece; 215,537 from Italy; 186,792 from Russia, and 33,617 from Turkey. One can see that the United States is continually receiving thousands who are heavily infected with intestinal parasites. While the *Trichuris trichiura* and the *Ascaris lumricoides* are the most prevalent and the immigrants are heavily infected with them, those who are infected with the *Ankylostoma duodenale, Oxyuris vermicularis, Strongyloides stercoralis, Dibothriocephalus latus,* and *Tænia saginata* are also coming to this country in considerable.

As previously stated, generally only two slides from each specimen were examined, and as no special methods of examination were used, the number of immigrants harboring intestinal parasites must have been considerably greater than the number found by my examination, and therefore the percentage of those infected must have been considerably higher. As 40.2 per cent. of all immigrants were found infected with one or more intestinal parasites, among the 1,041,570 immigrants coming to the United States during the fiscal year 1909-10, there were probably over 418,711 infected with intestinal parasites.

I wish to express my thanks to Dr. John F. Anderson, Director of the Hygienic Laboratory, Washington, for his advice regarding this work and the preparation of this paper.

THE TREATMENT OF ANEMIC ENTEROPTOTIC DYSPEPSIA.

By CHARLES F. PECKHAM, M.D.,

PROVIDENCE, R. I.

As an introduction to this subject, it may be as well to consider the functions of the stomach as they are known to-day. They are: (1) The storage of food; (2) The absorption of water in infinitesimal amounts; (3) The secretion of hydrochloric acid and pepsin in the proper proportions for the chymification of the food as its chemical character demands; (4) The conveying of this chyme into the intestine promptly, as chymification is completed.

As this last function is by far the most important in the average individual, it must always be borne in mind in the treatment of cases of functional dyspepsia. A weakness of this function is characterized by the following physical signs and symptoms: (1) The tendency to anemia; (2) The so-called habitus enteroptoticus; (3) The absence of real pain, but distress and pressure occurring irregularly; (4) The hyperacidity and relative hypersecretion. I say relative, because this is not a true hypersecretion, but the excess of liquid found in the stomach arises from the retention of the chyme beyond the time required for chymification. In other words, the stomach does not have the strength to keep itself clear of chyme. There are, in fact, a weakness and sluggishness of the gastric peristalsis that is analogous to the condition found in the heart's action, called bradycardia. This might be called bradygastria for the want of a better term.

Secondary duodenal and intestinal disturbances, due to the irritation of hyperacid chyme, form another very prominent group of symptoms. In fact, as a general thing, it is the onset of intestinal symptoms that first brings these cases under observation.

It is difficult to account for the amount of gas

belched in these cases on the theory of fermentation. This gas usually has the formula of atmospheric air. It is not carbon dioxide, and therefore cannot be the product of yeast fermentation. I am led to believe that this gas originates in two ways, namely, by insufflation through the esophagus and by osmosis through the stomach walls. The latter occurs when the intragastric pressure falls below that of the blood stream; and in some of these cases of atony the pressure may even be several millimeters of mercury below the atmospheric pressure when the patient is in the upright position. Whatever the cause of the accumulation of gas may be it always may be taken as an indication of a deficiency in the tone of the gastric musculature.

The position of the patient has a very marked influence upon this conveying function of the stomach. In the upright position, through fatigue of the gastric musculature, it is sluggish or suspended. In the recumbent position, however, the stomach renews its peristalsis and begins to empty itself. This accounts for the restless nights so much complained of by these patients.

In undertaking the treatment of these cases it is well to begin with a thorough physical examination in order to avoid the embarrassment of newly discovered complications, necessitating changes in procedures after a few months' treatment. It is especially recommended that the gastric contents, the feces, the urine, and the internal organs be gone over carefully and any deviation from the normal be noted for future reference.

The fact that chymification is generally normal, or, indeed, stronger than normal, must be borne in mind, and also, that hyperchymification is as deleterious to the intestinal welfare as hypochymification. Therefore, all digestants, hydrochloric acid, or drugs calculated to increase gastric secretion should be omitted, unless especially indicated.

These patients are usually made worse by the measures taken, through the advice of friends, for their relief. Acting upon the principle that any foods that cause distress, or that can be tasted in the eructations, must be omitted, these patients place themselves upon a starvation diet. Stories of subsistence for weeks upon milk without improvement are recounted with great pride and used as a clinching argument to substantiate the severe and malignant nature of the fancied gastritis or cancer.

We may next turn our attention to the following problem: What is the best method to follow in order that the gastric conveyer may take care of the chyme that must be transported to the intestines? This problem may be attacked in the following ways: (1) By decreasing the weight of the chyme without decreasing the number of calories. (2) By stimulating the gastric musculature, in the hope that it will normally take up its load under the resulting improved general nutrition. (3) By apparatus calculated to raise the lower border of the stomach, and allow it to work at a better mechanical advantage. (4) By placing the patient in such a position that the stomach will empty itself with the greatest possible facility. (5) By measures directed to the improvement of the patient's general condition. (6) By supplying the gastric movements artificially. (7) By the relief of intestinal symptoms. (8) By the operation of gastrojejunostomy.

The estimation of the amount of work done by the stomach in handling and discharging the food, and the effect that a low position of the stomach has upon the number of foot-pounds of energy required for proper function furnish a very interesting mechanical problem. The fact must be borne in mind that the normally placed stomach practically is emptied by gravitation, the subject being in the upright position. In the stomachs of enteroptotic individuals, if the distance of a horizontal line drawn through the pylorus to the lower border of the stomach, the weight of the food in the stomach, and the time required for the stomach to empty itself be resolved into foot-pounds per hour much of the distress and pressure complained of in these cases will be accounted for. The following formula may be used in this calculation:

$$D/12 \times T/60 \times W = \text{foot-pounds per hour.}$$

In which D equals the distance of the lower border beneath the pylorus, expressed in inches; T, the time required for the stomach to empty itself, expressed in minutes; W, the weight of the stomach contents in pounds.

Example.—Mrs. R. Diagnosis: Anemic enteroptotic dyspepsia. Gastric acidity, normal; diet, milk; has lost 10 pounds in three months; lower border three inches below pylorus; stomach empties itself in 100 minutes; amount of foods taken at the average meal, 12 ounces. Then:

$3/12 \times 100/60 \times 12/16 = 5/16$ foot pounds per hour.

This energy has been expended upon 12 ounces of milk, containing 243.6 calories, or 1/779 foot-pounds per calorie. If an equal amount of lean beef had been taken, containing 780 calories, it figures 1/2496 foot-pounds per calorie. In other words, about three times as much muscular energy per calorie has been expended in handling the milk meal.

We conclude from this example that all foods of low nutritive value and large bulk had better be excluded from the dietary. Naturally, water with a caloric value of nil, is the greatest offender in this respect. We generally find that these patients take a great deal of water with their meals. Many of them are the victims of an insatiable thirst, and the colder the water the better. If they do not take water, beer or the ubiquitous high-ball is made to take its place. Water, beer, soft drinks, tea, coffee, soups, and other liquids should be absolutely prohibited at meals. However, any of these may be taken two hours after meals in such quantities as to satisfy the patient's craving or thirst. Milk should be absolutely forbidden in every case.

The ordinary table diet, omitting all soups and other liquids, should be the rule. The diet may also include butter, soft fats, such as olive oil, but no pastry. The food should be finely divided and unirritating. In laying out a diet for these cases the principle must always be kept in mind: High nutritive value and small bulk.

Stimulation of the gastric musculature works well in some cases, but is a good deal like goading the tired horse. Among the drugs found useful for this purpose caffeine and strychnine may be prominently mentioned. Intragastric faradization may be tried, one electrode in a stomach tube of decinormal salt solution and the other over the epigastrium. So far as the patient is concerned this is a very disagreeable procedure. It makes a great impression upon patients of a neuropathic tendency, however, and never fails to create a very strong impression that a remedy is being applied directly to the seat of disease. Light massage of

the abdomen may be used; especially the manipulation known as vibration. External hydrotherapeutic measures, either the spray, with variable temperature, or the volumn, are also of some service. All of these methods should be used with caution. Deep manipulation of the cervical and thoracic regions of the back often gives good results. The intragastric douche may be tried in selected cases, but great care must be taken not to overtax the gastric musculature through the use of too much water.

Much ingenious apparatus has been devised for the purpose of raising the lower border of the stomach, and thereby decreasing the distance from the level of the pylorus to the stomach floor. In many cases its use is followed by marked improvement, but in others its application seems to do more harm than good. In reading the literature upon this subject one would be led to believe that the panacea for the long-suffering dyspeptic had been discovered. This apparatus varies in form, from the complicated plaster device of Rose, to instruments designed upon the lines of trusses made of hard rubber, with a plate that engages the abdomen below the umbilicus, and, by pressure, elevates the abdominal organs. Belts of linen or silk elastic webbing are of little use, as they cannot be worn comfortably by thin people, and most anemic dyspeptic patients are of rather spare habitus.

The adhesive plaster belt of Reed seems to give the best results. This is made of 3½-inch zinc oxide plaster, spread on moleskin, and its length should be 4 inches greater than the patient's girth. It should be so placed upon the patient as to form a girdle, coming over the flanks just above the crests of the ilium and crossing in front midway between the umbilicus and the pubes. A few strokes of the razor will be found necessary in most individuals. At the place of crossing the two ends are made secure with a common pin. The point of this is then cut off and a small piece of plaster applied to prevent injury to the clothing. Frequent applications of soap and water to this plaster improve its lasting qualities very materially. This should be worn continuously.

The treatment by position may vary in its extensiveness, from the rest cure of Weir Mitchell to weeding in the garden on the hands and knees. Prolonged rest in bed is not usually required, although the constant attention of servants and trained nurses that is necessary for its successful operation seems to be much appreciated by many patients. Various forms of gymnastics are beneficial, the principle being to bring the pylorus and the lower border of the stomach upon the same level and to combine this position with exercises designed to contract the abdominal muscles. Exercises imitating the play of children are often used, the fact being noted that the onset of symptoms has some direct connection with the time of puberty, and in the belief that dignity of deportment, with the attendant lack of use of the abdominal muscles, may be the cause of the trouble.

Reaching exercises may be prescribed. One very useful exercise consists in extending the arms above the head as far as possible, at the same time rising on the toes, then bending forward with the arms still extended and touching the floor with the hands, assuming the upright position and inflating the lungs at the same time, and then, with the lungs still inflated, the clinched hands are brought to the chest and the elbows extended behind the body as far as possible. While this is being done the entire muscular system is put under tension. In practice these exercises are found rather difficult of application. Where they can be carried out under the direction of a trained assistant they uniformly do good.

Measures directed to the improvement of the patient's general condition may be considered under the heads of hygiene and of therapeutics. Under hygiene may be mentioned the sojourn at some spa, where the waters are of a mildly alkaline reaction, or in some place where an out-of-door life, freedom from care and a general change of scene may be enjoyed. The patient's tastes may be consulted upon this subject, but any fishing or shooting trips must be well considered with the amount of fatigue in view. Traveling in the wilds of Maine is apt to be rather heavy work for these patients, unless the pace is made sufficiently moderate. A course of treatment on the lines of the fresh-air cure is often of great service, especially if the patient is much reduced physically.

Regarding drugs there is very little to be said. General tonics may be used. Phosphorus or the pyrophosphates of iron, alone or combined with gentian, may be tried. Tonics very rich in alcohol should not be used. Ammonium carbonate is a valuable stimulant, if one is needed.

The gastric peristalsis may be very closely imitated by massage of the abdomen. This is best performed within two hours after eating. This manipulation consists in gently stroking the abdomen from side to side with the flat hand. Its proper performance requires some practice. The error is usually made on the side of too much force and too rapid stroking. This method must be used with caution, especially if there is any tendency to a spastic condition in the colon, when it will cause discomfort and pain. It may well be combined with general massage. In the atonic forms of constipation it is the treatment *par excellence*, as under its use the bowels become more active and nutrition is very much improved.

Measures directed to the relief of the intestinal symptoms have a very important place in the treatment of these cases. There is always a certain irritable condition of the pylorus present, resulting from the irritation of the intestinal mucosa. This is very apparent in those cases that show a very marked increase in the degree of acidity of the gastric contents. This may even reach the point of spasm. Whenever nausea is present we may assume that there is an irritation of the intestinal mucosa or that this irritation has even reached the point of a catarrh. Bismuth is probably the most useful drug that we possess for the relief of this condition. It should be given in large doses and upon an empty stomach. Besides coating the intestinal mucosa and protecting it from the hyperacid chyme, it also acts as a very efficient intestinal antiseptic. The bromides are also of service, reducing the secretion of hydrochloric acid and allaying many of the reflex nervous symptoms, which are so troublesome in these cases. Belladonna also may be tried, always bearing in mind that many people are very susceptible to its action. Menthol and valerian may be tried. Among the alkalies may be mentioned sodium bicarbonate, calcium carbonate, and the alkaline mineral waters, omitting those that have any cathartic action. Small doses of chlorate of potassium may also be administered with improvement in many cases.

Cathartics should be avoided as much as possible. In patients past middle life their use may be necessary, but in most cases little permanent good can be accomplished while the patient is the victim of the cathartic habit.

The operation of gastrojejunostomy has no place in the treatment of anemic enteroptotic dyspepsia. Cases in which it is of benefit are few and far between, and in many cases I have thought that it has done irreparable harm. In cases complicated with ulcus, however, it may be performed after medical treatment has failed.

These patients are deserving of more attention than is usually bestowed upon them. In no other class of cases are a thorough physical examination and careful and painstaking diagnosis more important. Serious errors in diagosis are without excuse. For example, the diagnosis of anemic enteroptotic dyspepsia in the presence of gastrectasia is a fault that is apt to reflect upon our medical skill. The most common mistakes arise from confusing chronic catarrhal gastritis, dilatation of the stomach, and carcinoma with anemic dyspepsia—in other words, an organic with a functional disease.

These cases belong to that class known as the physically deficient. They are, as a general thing, poorly fitted to fight the battle of life. Nutrition with them becomes a positive burden. They are apt to be the subjects of tuberculous infections or of other low grades of inflammation. They show a marked tendency to develop psychopathies, neuropathies, drug habits, and alcoholism. They are active mentally and are very quick to detect any inconsistencies in the statements made to them in the course of their treatment. They are constantly in search of the royal road to recovery, and the amount of time that they will spend in efforts to save themselves mental and physical labor is remarkable. It is very difficult to get them to follow a régime with any degree of consistency. Their idea of life makes it, to them, one of constant compromise.

Many of the results of treatment may be called truly brilliant, but, at times, our best efforts will end in failure. We should regard these cases as mechanical problems, in which we must so handle an insufficient gastric conveyor that it may serve the requirements of the bodily nutrition.

ALCOHOLISM AS A COMPLICATING FACTOR OF ANESTHESIA.

By F. HOEFFER McMECHAN, A.M., M.D.,

CINCINNATI, OHIO.

STAFF ANESTHETIST TO THE CITY, ST. MARY'S AND THE POLYCLINIC HOSPITALS.

Alcoholism is perhaps the most annoying complicating factor of anesthesia. The percentage of alcoholics coming to operation in the surgical clinics of the larger municipal and charity hospitals is deplorably high and constant, more especially among the male patients, although the same complication is not a negligible problem in the opposite sex. This fact is so prevalently recognized that the anesthetic charts of many operating clinics call for the report of alcoholism as present or absent, and, if found, of what character.

The recognition of alcoholism as a complicating factor of anesthesia, previous to any attempts at the induction of narcosis, will enable the anesthetist to modify routine technics of anesthesia, according to the exigencies of individual cases and the requirements of certain operative procedures. Unless the alcoholic complication is prognosticated, the induction of narcosis will be beset with unpleasant difficulties, and its conduct become unsatisfactory to the operator and the best interests of the patient. Consequently the presence of alcoholism should always be noted by the nurse or intern in charge and called to the attention of both the operating surgeon and the anesthetist. If no such precautionary measure has been taken, the anesthetist must at the time of operation determine for himself, by tactful but searching questions, the exact quantity and frequency of alcoholic consumption, in order to judge the alcoholic status in its relation to the prospective narcosis. Occasionally surgeons who have some knowledge of their patient's character may be misled with regard to the alcoholic problem involved. It is not unusual in municipal and charity hospitals to have the unpleasant duty of anesthetising patients for emergency, as well as routine operations, who are drunk; in some instances maudlinly combative, in others bordering on the verge of delirium tremens. *Acute alcoholism as a complicating factor of anesthesia, contraindicates any operative procedure, except in life-saving emergencies. Chronic alcoholism demands preliminary medical treatment before any operative interference is justifiable.* Such prophylactic treatment, no matter how thoroughly carried out, may not always prove altogether of avail in avoiding postoperative complications, but it is a necessary precautionary measure to safeguard the patient's interests.

While hospital records show a large number of cases transferred from the "strong wards" to the various surgical services for operation after the subsidance of tremor symptoms, without postoperative exaccerbation of the condition, still the recurrence of delirium in alcoholic subjects is a constant menace and must be duly considered in concluding to operate. Nor does abstinence in confirmed alcoholics, for some months previous to operation, obviate the alcoholic complications of anesthesia. For such saturation the use of the Lambert method, the complete withdrawal of alcohol, the exhibition of bromides, chloral, and ergot in conjunction with hypodermoclysis, will be found invaluable in putting the confirmed alcoholic into fair condition for operation under inhalation narcosis, or in combating the exigencies of delirium tremens, should this condition develop postoperatively.

The foregoing emphasizes the distinctive value of spinal and regional analgesia for operative procedures in alcoholic subjects, particularly when such surgical intervention is necessitated by life-saving emergencies and the alcoholic symptoms are pronounced. Under these circumstances spinal analgesia (Corning), regional analgesia (venous-Bier; arterial-Ransohoff), nerve blocking (Crile), and infiltration *en masse* (Matas), separately and in conjunction, offer methods which not only do not exacerbate the alcoholic condition, but in some measure decrease its effects and counteract any tendency to shock from the necessary manipulative and operative trauma.

Martin, alluding more especially to genito-urinary and rectal surgery, says: "Alcoholics are exceeding difficult to anesthetize and require excessive quantities of ether to obtain relaxation. They breathe badly and cyanosis supervenes rapidly, with consequent turgescence of the parts under operation. Hemorrhage is free and may inconvenience the op-

erator. These patients under spinal analgesia are quiet. There is complete muscular relaxation, with no congestion of the operative field and little or no troublesome hemorrhage."

Cases of fracture and dislocation, complicated by alcoholism, if the stupor of the debauch does not give sufficient narcosis to deaden the pain or relaxation enough to permit reduction, may be readily handled according to the method of Dr. Quénu (Paris), who injects mild cocaine solutions into those muscles which oppose reduction. While analgesia always produces flaccidity of musculature in alcoholic subjects, inhalation narcosis, on the other hand, is prone to produce jactitation and spasticity. However, in the large proportion of routine operative procedures it is possible to satisfactorily anesthetize alcoholic subjects by inhalation narcosis, if the presence of alcoholism is known and the proper methods for combating the complication are utilized.

Unfortunately gas-oxygen, at present considered the safest anesthetic method in vogue, is not very satisfactory or serviceable in anesthetizing alcoholic subjects. The reasons why are apparent. Nitrous oxide produces profound cyanosis, and alcoholics are prone to become cyanotic under all anesthetics, but more especially under gas. The addition of oxygen, even in low percentages, while it may have some effect in obviating the cyanosis, also brings the patients around, and it is exceedingly difficult for even expert anesthetists to carry alcoholics through operations requiring any length of time, under gas-oxygen narcosis, without having undesirable rigidity of musculature, arrest of respiration, and the inconvenience of steering between dangerous cyanosis and too light an anesthesia. This has also been the experience of such continental authorities as Hewitt, Buxton, Bellamy-Gardner and Blumfeld, whose written details on this phase of narcosis are of considerable interest. "In certain exceptional cases (alcoholics) nitrous oxid seems incapable of producing more than an analgesic state. If the gas is given without oxygen, clonic and tonic spasm come about abnormally early and cut short the administration; while if oxygen is mixed with nitrous oxide, the anesthetic element may be insufficient to induce true narcosis." (Hewitt.) That spasticity of musculature may sometimes be a purely alcoholic reaction during anesthesia is evidenced by its constant association with alcoholism, and its persistence during operations, despite the use of different methods, agents, and depths of narcosis.

In a personal communication, Dr. Charles K. Teter of Cleveland, Ohio, whose apparatus for gas-oxygen narcosis, and his vast experience with that method, have made him a foremost authority on the subject in America, contends that alcoholics are by far the most difficult subjects to anesthetize with gas-oxygen, but considers that with expert administration and cooperation between the surgeon and anesthetist even the worst cases may be handled with fairly satisfactory results. He also insists that in the presence of intercurrent complications, gas-oxygen, particularly in alcoholics, is the method of choice, in view of its increased safety to life during its administration, and more especially for its beneficent influence on postoperative recovery. While gas-oxygen will be used in exceptional cases to anesthetize the alcoholic, it is doubtful whether many surgeons will find it sufficiently satisfactory to encourage its routine use for such individuals. The gas-oxygen-ether sequence has this advantage, that the cyanotic effects of the nitrous oxid may be somewhat controlled by the concomitant use of oxygen, while the almost immediate addition of ether, in many instances, enables the anesthetist to satisfactorily overcome the usual combativeness of the alcoholic subject during the period of excitement. Also gas-oxygen narcosis, supplemented by ether as required (Gatch-Teter) is a feasible method in obstreperous alcoholics who cannot be satisfactorily controlled by gas-oxygen alone. However, ether by the drop, much less by any closed method, produces considerable and sometimes excessive cyanosis in alcoholics, so that the gas-oxygen-ether sequence, while serviceable, is not always entirely satisfactory as a routine method. "Alcoholics are best given nitrous oxid, followed by ether; but they often become greatly cyanosed, and to relieve this condition, chloroform must be given for a time, even if ether be subsequently resumed. As a rule oxygen, given with the ether, prevents this cyanosis, unless it is due to severe spasm. I have found that some confirmed alcoholics remain restless and rigid even during the profound narcosis." (Buxton.)

Ether by the drop method (Magaw), while obviating to some extent the occurrence of dangerous cyanosis, unduly prolongs the period of excitement during induction, and does not always give the requisite flaccidity of muscles demanded by the convenience of the operator, nor the clear air-way so necessary for the safety of the patient. Chloroform by the drop or vapor method is ineffective in the usual dosage or percentages, and, when used alone, is somewhat dangerous if pushed to effect. The point of danger lies in the propensity of alcoholic subjects to fixation of the chest and arrest of respiration, a condition which arises under all methods of narcosis complicated by alcoholism, but which is most dangerous to life when by its occurrence the intrapulmonary tension of the inspired chloroform is increased. "The author (Hewitt) has had to administer 5½ ounces of chloroform in 1¼ hours to an alcoholic male of 56 years. It is occasionally difficult, if not impossible, to secure total muscular relaxation in patients of this class, and reflex movements, during operations upon sensitive parts, may obstinately persist, even though dangerously large quantities of the anesthetic be administered. In confirmed alcoholics the stage of muscular excitement is usually prolonged, and at all events, with chloroform there is need for caution during this rigidity and irregular respiration. * * * (Under chloroform) other things being equal, the greater the vigor of the patient, the greater will be the tendency to development of muscular spasm, not only of the extremities, but also of the respiratory muscles, masseters, muscles of the floor of the mouth, larynx, and other parts. It is in this way that chloroform kills in the perfectly healthy subject. The fatal symptoms commencing when the cornea are sensitive and the circulation failing before the anesthetist can re-establish breathing. * * * It is by no means uncommon for clonic muscular phenomena to arise during the second and third stages of chloroformization, more particularly in cases in which the breathing is somewhat obstructed by stertor, jaw spasm, or laryngeal closure. In some of the recorded cases of this kind patients are reported to have had a 'fit' or to have been attacked by 'epileptiform convulsions.'" The danger arising from the necessary concentration of the anesthetic to produce surgical narcosis

is further emphasized by Gardner: "The author (Bellamy-Gardner) has known it impossible in the worst cases (alcoholics) to maintain anesthesia, except with chloroform vapor so concentrated by wrapping a towel over a Skinner's mask, that the same patient would have been overdosed past the hope of resuscitation if they had not been addicted to alcoholic intemperance."

The advent of ethyl chloride has given the anesthetist a preliminary anesthetic which makes the anesthetization of alcoholics somewhat easier and a trifle more satisfactory. Ethyl chloride does not produce cyanosis, and when properly administered has only a mildly depressant effect upon the circulatory system. Immediately followed by ether (drop method) or more preferably by a synchronous use of both agents after unconsciousness has been established until surgical narcosis results, this method obviates in the majority of instances all disconcerting cyanosis and unpleasant combativeness on the part of alcoholic subjects.

However, even this sequence is not entirely successful in some of the worst cases, and in these very exceptional instances the following technique has been found safe and reliable in the most obstreperous subjects. The ethyl chloride is followed by a C_1E_5 mixture by the drop method. The addition of chloroform to the ether in any proportion not exceeding the accepted ratio of two to three, meets the demands of anesthetizing alcoholics most successfully. The added chloroform counteracts, by its slightly depressant effect upon the circulatory system, the cyanotic tendency of the ether to venous engorgement, besides obviating to a remarkable degree spasticity of musculature and inconvenient neural reflexes. Occasionally after the preliminary use of the C_1E_5 mixture, until surgical narcosis supervenes, the anesthesia may be continued with drop ether alone, but the worst subjects may require the mixture throughout. With this sequence and combination it is not only possible to anesthetize recalcitrant alcoholic subjects with ease, rapidity, and safety, but it is also possible, in any case to carry the lightest degree of narcosis which may be consistent with the requirements of the operation in hand.

It happens frequently that during the conduct of narcosis in alcoholic subjects, despite expert administration, jacitation, spasticity, and clonic spasm develop from operative trauma, certain manipulations or turgescent cyanosis. Under such circumstances it has been the experience of Rowell and Kingsford that under chloroform or ether narcosis, the spraying of a few cubic centimeters of ethyl chloride upon the mask will almost immediately relax musculature and quiet jacitation. A perfecting detail of this method is the concomitant use of oxygen to control any imperiling degree of cyanosis which may arise during the conduct of narcosis. Oxygen not only renders anesthesia safer to the patient, but even when used in low percentages has a peculiar effect in maintaining the physiological balance of the gaseous constituents of the blood. It not only promotes the entrance of the ether vapor into the circulation, but also assists in its excretion by keeping the output of carbon dioxide to practically its physiological standard. The concomitant use of oxygen in this manner is not only more rational, but in the experience of expert anesthetists, more successful in obviating and combating anesthetic dangers than the concomitant use of carbon dioxide.

Postoperative recovery is exceptionally rapid in alcoholic patients, who are often able to talk and look about them within two or three minutes after withdrawal of the anesthetic. Postanesthetic vomiting is a rare after effect, and aside from suppression of urine or the supervention of delirium tremens or pneumonia there are few complications. Now that it is possible to establish the gauge of kidney function, the urinary output test should be used preliminary to operation on alcoholics whose history or pre-operative condition make them hazardous risks.

As Bellamy-Gardner has suggested, some alcoholic patients cannot be satisfactorily anesthetized by any known method, and in operating upon subjects of known alcoholic excesses a method of fixation to the table recently illustrated by Herb, Rush Medical College, and also in routine use at Bethesda Hospital, Cincinnati, Ohio, is remarkably effective. A heavy canvas surcingle is circled about the patient and table, just above the knees, and drawn sufficiently taut not to be uncomfortable, but to prevent untoward movements during the excitement stage of narcosis. The wrists are either held firmly to the sides of the hips by leather wristlets, joined by a strap under the gluteal fold, or may be circled by strands of twisted gauze, tied with an inch leeway, so that no movement of the patient can impede circulation by tightening the loop. The gauze is passed under the thighs or is tied to the table so as to flex the forearm on the biceps. The wristlets must have automatic catches which can be instantly released, and the gauze must be tied in single bow knots, so that in case of emergency, when artificial respiration must be resorted to, the arms of the patient may be quickly released. Bimanual pressure over the lower ribs is very effective in re-establishing respiration which has been arrested by spasmodic fixation of the chest.

The suggested restraint is not only harmless and convenient, but it also prevents any untoward movements on the part of patients at any stage of narcosis or operation, a precaution that is well worth taking in advance when confirmed alcoholic subjects are concerned. Also the customary stirrups attached to operating tables lend themselves poorly to securing alcoholics in position for perineal or rectal operations. The Clover-clutch, carefully adjusted and safely anchored; the Bierkoff stirrups, or the shoulder-strap leg holders, which flex the thighs on the abdomen, are decidedly preferable in use. Other stirrups, which secure the required position by straps about the ankles and insteps, give the patients a powerful purchase for pushing themselves up the table. Preliminary hypodermic injections of morphine alone, or in combination with hyoscine, or atropine are a serviceable routine in all alcoholics, not presenting symptomatic contraindications to the drugs mentioned.

Postoperatively, should there be suppression of urine, sparteine sulphate, if used in sufficient dosage, is a specific. Also, if there is likelihood of delirium tremens supervening, appropriate medical treatment should both anticipate and immediately follow the operation and be pushed to effect.

While attention to all these details will make the narcosis safe for the patient, as convenient and satisfactory as possible for the operator, still expert anesthetists will always feel, after gruelling experiences with alcoholism as a complicating factor of anesthesia, that it is deplorably prevalent and would gladly be dispensed with, could such an improbable event occur.

639 West Seventh Street.

TINEA VERSICOLOR IN THREE SISTERS; REVIEW OF THE UNUSUAL FEATURES OF THE DISEASE.*

By FRANK CROZER KNOWLES, M.D.,

PHILADELPHIA.

INSTRUCTOR IN DERMATOLOGY, UNIVERSITY OF PENNSYLVANIA; DERMATOLOGIST TO THE PRESBYTERIAN, THE CHILDREN'S, AND THE HOWARD HOSPITALS; ASSISTANT DERMATOLOGIST TO THE PHILADELPHIA GENERAL HOSPITAL; DERMATOLOGIST TO THE CHURCH HOME FOR CHILDREN, THE BAPTIST ORPHANAGE; ASSISTANT DERMATOLOGIST TO THE DISPENSARY OF THE PENNSYLVANIA HOSPITAL,

AND

EDWARD CORSON, M.D.,

CYNWYD, PA.

ASSISTANT DERMATOLOGIST TO THE DISPENSARIES OF THE PRESBYTERIAN AND THE CHILDREN'S HOSPITALS.

Robert Willan suggested the term pityriasis versicolor in 1799. Eichstedt of Griefswald, in 1846, demonstrated that the disease was due to the growth of a fungus. Charles Robin in 1853 classified the organism as the species *Microsporon furfur*. It has been exceedingly difficult to grow this organism. Sehlen obtained cultures in 1889; Sehlen and Unna cultivated the fungus in 1890 in five out of seven cases, but were unable to infect anyone with them. Matzenauer and also Gastou and Nicolau have cultivated the microsporon. Spietschka found that, while cultures in the same media were identical in twelve cases, when the medium was varied very different looking cultures resulted. Castellani has pointed out that there are three different varieties of tinea versicolor, the white, the yellow, and the black. Lutz points out that in the colored races it produces white or, where the fungus is very abundant, gray discoloration of the skin. The organism attacking the exposed portions of the body frequently produces an eruption of a much darker color than that of the covered parts, as shown in Gottheil's and also in Allen's cases.

Tinea versicolor involves almost invariably the trunk to the exclusion of other portions of the body. In extensive cases, or at times in those of less extent, the disease is found on the upper arms and the covered portion of the neck. Those who see a considerable number of cases of this fungus disorder realize the fallacy in attributing a relationship between the condition and the general health of the individual, particularly in regard to its association with tuberculosis. Daguet and Hericourt, however, take a different view and believe the *Microsporon furfur* produces phthisis, in some instances, as they found this organism in the diseased tissues and the injection of the same rendered guinea-pigs and rabbits tubercular. No other investigators have reached the same conclusion.

Although in the great majority of the cases the trunk alone is involved, in certain instances other parts may be attacked. Dubois-Havenith observed it covering almost the entire arm and forearm to the wrist, and on the neck. E. O. Smith has noted an instance in which the dorsal surface of the feet were alone attacked by the disease. Crocker has seen the condition in the popliteal spaces in three instances and on the elbows twice. Allen pointed out that there is frequently found in the pubic region, both of men and women, one or more patches of tinea versicolor.

A few authors have reported cases in which the exposed portions of the body have been attacked by the fungus. Biart has found the disease on the face. Allen observed several instances in which the face was involved. Powell states that in Assam it is very common on the face. Unna cited the case of a bearded man, the lower portion of whose face was attacked, and quoted his own case to the same effect. Payne found the *Microsporon furfur* abundantly in the scales from the scalp and beard, where there was apparently only a simple pityriasis; the trunk was also attacked. Delepine recorded a case of tinea versicolor occurring in a man with pulmonary tuberculosis; the face, thorax, the abdomen, and the palm of the hand were attacked by the organism. Gottheil related the case of a Cuban physician who had the disease on his left palm, lasting for fifteen years.

Experimental inoculation has been successfully performed in a few instances. Köbner succeeded in infecting himself over the sternum and then transferred the growth to rabbits. Huble produced the eruption by rubbing the scales of the disease fixed in glycerin thoroughly into the skin until the surface became red. He also produced the disease by raising the epidermic scales with a lancet and keeping the pityriasis scales in glycerin in contact with the skin. Pityriasis versicolor was plainly visible to the eye in from two to six weeks.

One is impressed after a careful review of the literature on tinea versicolor with the few cases of contagion reported, evidently showing that the condition is but slightly contagious or that instances of this character have not been reported. A. Coffin met with the case of a woman who contracted it from her husband seven months after marriage. Huble has found nine instances of transmission of the disease from the male to the female or the reverse. He thinks that the disease in these cases was transmitted by the intimate contact of sexual intercourse. Two other cases are also cited of mediate contagion, clothing being the intermediary. Lancereaux describes his own case. After examining some of the scales under the microscope from a case of this disease he placed the remainder in a piece of paper in his waistcoat pocket. When over a month had elapsed and while still carrying the fungus in his pocket he developed a typical case of tinea versicolor upon his chest. Jonathan Hutchinson recorded an instance in which the husband transmitted the disease to his wife, the pubic region in each being attacked.

A few articles have been written upon the epidemics of tinea versicolor occurring in institutions, among prostitutes, and in various armies. Nichols reported that in 709 male patients examined in an institution 42 had this disease. Matakieff reported an infection of 6.25 per cent. among 80 patients at a hospital in Nancy, and the infection of 10.8 per cent. among 1,201 patients in another hospital. In the Long Island Hospital for the Insane Winfield found an infection of 1.29 per cent. of 1,084 patients; 43.8 per cent. showed infection in the pubic region. In an apparent epidemic of the infection in Hamburg in 1879 Una found 20 per cent. of the 82 prostitutes infected. Huble examined carefully 2,360 soldiers between nineteen and twenty-four years of age, and discovered tinea versicolor in but 39. In a part of India 4 per cent. of 2,540 prisoners were infected (Bulkley).

Cases of the authors: Case I.—Fannie W., nineteen years of age, came to the skin dispensary of the Pennsylvania Hospital on June 1, 1910, with an eruption of some months' duration upon the

*Read before the Philadelphia County Medical Society, April 26, 1911.

shoulders and the upper part of the back. The lesions were typical in every way. A microscopical examination demonstrated the *Microsporon furfur.*

Case II.—Ida W., seventeen years of age, came to the skin dispensary of the Pennsylvania Hospital on June 27, 1910, with a typical outbreak of some months' duration upon the upper part of the back and the chest. The fungus was found microscopically.

Case III.—Sarah W., sixteen years of age, came to the skin dispensary of the Pennsylvania Hospital on June 27, 1910. The eruption was noted on the chest and the upper portion of the back. The microscope gave a characteristic picture.

The three sisters were all born in Russia although Philadelphia has been their place of residence for some years. They are healthy, but being extremely poor their cleanliness was not such as might have been desired. They occupied the same bed and occasionally used the same towel.

Comparatively few cases of tinea versicolor are seen by the dermatologist; out of 4,060 patients observed by one of us during 1910, in hospital and private practice, there were but eleven cases of this disease. The statistics of the American Dermatological Association for the year 1908 show that out of 36,500 cases of skin diseases reported there were but 211 instances in which tinea versicolor was noted, or 0.605 per cent.

In conclusion we wish to express our thanks to Dr. C. N. Davis for the prvilege of reporting the cases.

Association of Measles and Scarlatina.—Hutinel states that if measles precede scarlet fever, the prognosis, according to certain clinicians, is not bad; in fact, the succeeding scarlet fever being of a mild type. Other clinicians hold the reverse. The simultaneous appearance of measles and scarlet fever does not make the prognosis grave, but if measles should follow scarlatina the danger is greater; the more so the nearer the measles is to the scarlet fever.—*Paris Médical.*

THE SIGNIFICANCE OF RELAPSES.

By O. L. MULOT, M.D.,

BROOKLYN, N. Y.

The possibility of the occurrence of a relapse in the course of certain diseases must always be duly considered in making the prognosis. Many cases that have been following the usual course of the disease and giving the medical attendant every reason hopefully to look forward to a recovery, by the occurrence of a relapse change the whole picture and terminate fatally. Even if a fatal termination does not always occur, the economy, weakened by the battle with the first assault of the disease, is indeed poorly fitted to fight this second attack, and if the patient does not succumb to this second attack, it gives him a much longer and more precarious convalescence than he otherwise would have had. It is, therefore, quite natural that this occurrence is one of considerable interest and importance. There are many who ask themselves, and quite seriously, too, "Was it my fault? If I had not done this and instead had done that, perhaps this relapse would not have occurred." Not alone is this misunderstanding about the mechanism of relapse prevalent among the rank and file, but we even find it among the leaders in the profession. Whenever we read about some new method of treatment or feeding, in a particular disease, space is devoted to the percentage of relapses and this percentage becomes either a point of attack or an element of defense for or against the particular method. I am far from ready to accord to this percentage of relapses such an importance, and I do not believe that it should be the touchstone of methods. I do not see how relapses can in any way be due to sins of commission or omission, either on the part of the medical attendant, the nurse, or the patient.

In order to substantiate such an unorthodox belief, we must understand what really constitutes a relapse. An exacerbation, or a sudden turn for the worse, in a case that has been running the usual course of the disease, these we must not confound with or call a relapse. Brouardel and Thoinot, in an article on typhoid fever, quote Hutinel's definition of a relapse in that disease: "A relapse in typhoid fever is the reproduction, after the apparent establishment of convalescence, in whole or in part, of the symptoms that characterized the first attack. We cannot speak of a relapse unless the morning and evening temperature, for at least two days, has flucuated near the normal." With particular stress he sounds the warning not to confound recrudescence and subsequent attacks with a relapse. The recrudescences, which are always accompanied with an elevation of temperature and a relative aggregation of all the typhoid symptoms, are very common during the period of defervescence of typhoid fever, but these cannot be considered as relapses in the true sense, for there has as yet been no real beginning of convalescence. Hutinel then takes up in his usual lucid style a discussion of the various temperature curves of relapses: the reappearance of the rose spots, the diarrhea, the tumefaction of the spleen, and the nervous phenomena. While we are here concerned with the question of relapses in general and not particularly with those of typhoid fever, this definition and the relapses of this disease will serve us well as typical for general consideration. With a definition that clearly establishes the limits of our

subject we can now take up the theories commonly held concerning the mechanism.

About this mechanism there are four principal theories. (1) Greisinger's: "A relapse is a new *ex corpore* infection. (2) Hamernyk and Macaglan's: "An infection of the patches and follicles that have escaped the first onslaught and have become infected by material coming from those diseased by the primary infection." (3) Jaccoud's: "The relapse is a peculiar evolution of the disease, expressing itself in two or more stages." (4) Sanarelli's: "The persistence of the germ at some point in the economy, which reestablishes the disease, an autoreinfection." Against all of these, except the last, one can raise valid objection to their correctness. If the first, that of Greisinger, be true, then carelessness to remove this possibility of *ex corpore* reinfection must lie as a terrible indictment. The second theory, that of Hamernyk and Macaglan, is still harder to accept. We know that certain patches do escape the first onslaught of the disease, but why this secondary infection does not occur in every case, since in each case these are exposed to the infecting substance, this theory does not satisfactorily explain. During the period of incubation and subsequently there is a very general infection and a swarming over the whole economy of the bacilli, and why these patches escaped this first attack only to succumb later is not made clear at all. There is nothing alluring in this explanation. The third theory, that of Jaccoud, is simply one of words and tells us nothing and therefore there is nothing to discuss. The fourth theory, that of Sanarelli, is very generally accepted; and yet, while apparently based upon laboratory experiments, these experiments prove nothing, and worse still he misinterprets them. His theory does not tell us why the pathogenic germs, in a certain corner of the body, should escape extinction. This theory does not help us to an understanding of the mechanism of the occurrence. To understand this we need no laboratory experiments.

Before we go further with our discussion we must recall that relapses occur only in the course of diseases of microbic origin and for a better understanding of what will be said later on it is necessary to study the *modus operandi* of cure in these diseases. For that we need not go over the various steps and means which the economy brings into play in fighting infection, for we are interested in a condition which has resulted from the failure of the economy to defeat infection, and, therefore, must study the tactics of the economy in dealing with an enemy fully established within its domain. The first repellants which the economy puts forth against infection, of course, are continued, and whether the elexins are formed in the leucocytes and liberated when these break down, as Metchnikoff claims, or are always present in the blood, helps us little; the main point is the formation by the economy of the particular antitoxin which must determine the end of the infection. Now, if this antitoxin is not sufficient, we simply have an arrest and not an extinction of the process. This is what occurs when we have a relapse; these arrests are familiar clinical occurrences in diphtheria when we do not use a sufficiently large initial dose of antitoxin. Relapses are more frequent in the diseases in which the formation of the antitoxin occurs late, and this explains why this event is so much oftener observed in typhoid fever and the economy is sapped and exhausted by the long continuance of the infection and the fever. How a nidus of germs should escape the antitoxin substance, which is carried by the blood to every part of the body in the same percentage, as Sanarelli imagines in his theory, is hard to understand, does not seem reasonable, and cannot be proven by laboratory experiments.

Viewed in this light, we can now see how very little we can do to assist or impede this formation of antitoxins. The lesson we should draw from this is that particularly during the period of defervescence we must do all we can to husband the strength of the economy and avoid every thing that might in any way divert its efforts. Too often at that time do we relax our orders about visitors. The alimentation should be particularly supporting, but must never tax the system and the patient must be guarded against meddlesome nursing, and for the rest we must trust to the economy to put forth an effort adequate to the entire extinction of the infection, and should it fail in this we can console ourselves that its failure is not due to any sins of omission or commission on our part.

424 Halsey Street.

REPORT OF A CASE OF PERISINUS ABSCESS, SUPPURATIVE LATERAL SINUS THROMBOSIS, JUGULAR LIGATION—RECOVERY.

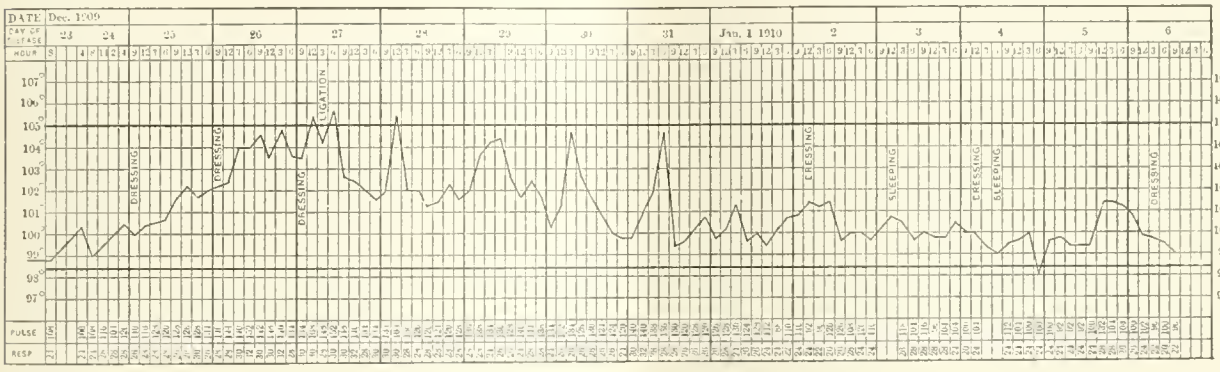
By CORNELIUS DOREMUS VAN WAGENEN, M.D.,

NEW YORK.

Elsie C., age 6 years, school girl, was first seen by the writer some eighteen months before the onset of the series of events herein related. She was then a pale, highly nervous child and decidedly incorrigible. Examination disclosed hypertrophied faucial tonsils and a well developed adenoid. Their early removal was advised, but the patient passed out from observation until December 7, 1909, when the mother, in great anxiety, again sought advice. Sore throat, the history of all previous sicknesses, had been the onset in this instance and was quickly followed by pain in and discharge from both ears. After five days of home treatment, delirium had developed during the previous night. The right ear was the seat of a moderately severe acute purulent inflammation. The left ear presented the classical clinical picture of a large, tense, postauricular and mastoid abscess, while a profuse discharge was issuing from its canal. Choreiform movements of the head and the upper and lower extremities were present; the child looked septic, and was evidently in considerable distress of mind and body. Prompt surgical measures were obvious. She was admitted to the writer's care, in the service of Dr. Arthur B. Duel, at The Manhattan Eye, Ear, and Throat Hospital.

Operation 8 P.M. Ether narcosis. At the onset this case aptly illustrated the caution necessary in making the initial incision, especially in children. Had the writer opened the abscess with a single bold sweep of the knife, as practised by some operators, the blade would have immediately encountered and undoubtedly freely incised the exposed lateral sinus, which, placed rather far forward and in effect subcutaneously, occupied the center of a large perisinus abscess. Mastoidectomy, including a thorough inspection of the zygomatic cells, was rapidly performed. The sinus, when cleaned up, exhibited two opposing pinhead spots, of a very dark and dubious appearance, situated about the

center of the 1½ cm. of exposed sinus wall. While one of the resident staff was removing the outer dressing, on the third postoperative day, a sudden hemorrhage saturated the gauze packing in the mastoid wound; yet, upon its careful and expectant removal, no bleeding point could be found. The writer then took personal charge of subsequent dressings, and, upon a recurrence of the bleeding a few days later, discovered its source and mechanism. Recalling the intractability and highly nervous state of this child, her aversion, amounting to terror, at the suggestion of a dressing may be easily imagined. Even the writer's step, approaching the ward, would evoke a crisis. While inspecting the open wound a complete collapse followed by a sudden and violent distention of the sinus was observed, synchronous with the acts of crying and screaming. It was noted that, during the latter phase of this cycle, one of the two dubious points above mentioned was forced open. A lightly applied tampon promptly controlled the bleeding. Subsequent dressings at increasing intervals were resorted to, but with four recurrent hemorrhages of the same brief character. A strip of sterile vaseline gauze was then applied to the vulnerable wall, in the hope of obviating the tearing of the sinus from the adherent dressings by the aspirating action of the pleural cavity during crying. Unexpectedly this strip became firmly adherent to the wall, while permitting an easy removal of all dressings from about a reinforcing tampon. On December 25, while redressing her, an unusually violent paroxysm of crying suddenly ensued. Not only was the tampon forced from under the restraining finger, but a stream of blood was thrown onto the adjoining bed, while the two, hitherto improved, spots of weakness on the wall were converted into one comparatively large ragged opening. Complete occlusion of the sinus was indicated. It is well to note here that with these exceptions the case had been making a slow and uneventful recovery. The right ear, under myringotomy and appropriate after-treatment, had long since reached resolution. The temperature had remained normal. Partly to relieve cerebral blood-pressure, partly to allay restlessness, the child was at first allowed to sit up in bed, but was soon given the freedom of the ward, where she became surprisingly quiet and manageable. Under the observation of Dr. Philip Van Ingen, attending physician, her general condition had shown improvement, though she was still quite excitable. Just prior to the sinus rupture the temperature curve had shown a slight elevation, but any significance this might have had was lost sight of in the rapid development of the case. Reference to the accompanying temperature chart will be of aid in following the progress of the case toward its crucial moment. During the rise to the 104° F. mark reached the following afternoon there were no other symptoms. The patient slept well and retained all nourishment. With the higher elevation simple nausea appeared, but whether due to interval medication, interdicted but continued, could not be determined. During the second night 105° F. was reached, followed during the next morning by several rapidly occurring remissions and elevations. There were nausea with vomiting, pain in the neck and left side of the head, and the formation of cutaneous metasteses, the forerunners of decubitus. Dr. Duel then saw the case in consultation and advised immediate operation for the isolation of infecting area. Operation. 4 P.M. December 27. Ether narcosis. A short incision was made along the anterior border of the left sterno-cleido-mastoid muscle. An enlarged superficial cervical gland momentarily retarded progress, and then a rapid dissection was carried down onto the junction of the common facial and internal jugular veins. Neither vein presenting anything abnormal, the latter was ligated in two places, just above its facial anastomosis and divided between ligatures. The sinus was then further exposed and explored without return flow. A gauze tampon to the torcular opening and a gauze drain to the bulb completed the operation. Dr. Jonathan Wright later reported streptococci and diplococci in the specimen of sinus wall and contained clot submitted to him for examination. A glance at the temperature chart will concisely illustrate the progress toward convalescence which was indeed uneventful. The child was finally discharged, at parents' request, from hospital treatment but with the hypertrophied tonsils and adenoids still untouched and still a menace.



Again she disappeared from observation until September 14, 1910, when she was brought back to the hospital with an acute suppurative postauricular process under the mastoid scars and requiring relief. Operation 3 P.M. same day. Ether narcosis. The knife opened a pocket of pus, afterward reported as pure streptococcus in origin, bathing alike the dura and a confusing amount of new bone, already somewhat involved in the suppurative process. Recovery followed a thorough evacuation of all diseased tissues. Determined not to again permit her discharge from the hospital with the hypertrophied tonsils and adenoid *in situ*, the writer was finally able to transfer her, under the rules of the institution, to the service of Dr. Walter F. Chappell, where tonsillectomy and adenectomy were performed.

A review of this case would seem to provide more points of interest than it is commonly the mis-

fortune of these patients to exhibit. Naturally the contention for early tonsillectomy and adenectomy receives additional confirmation. The sinus being found so exposed and displaced under pressure so far forward renders the determination of its original position, in respect to the antrum, one of doubtful accuracy, but the absence of a purulent focus in the bulb and the condition of the sinus wall and bony environment would seem to indicate an unusual relation and path of infection. The aspiration of the closed chest need not of itself arrest our attention, but when it so profoundly influences the course of disease, as in this instance, it becomes a matter of grave moment. The means adopted to combat this menace to the weakened sinus wall may seem crude and insufficient, but were the best suggested by the writer's judgment and experience. It is doubtful whether their earlier use would have met with any greater success, as they seem to have exerted only a deterrent effect upon the ultimate and apparently inevitable outcome. By this it is not intended to infer that, in the presence of every damaged sinus wall, palliative treatment should at once be discarded and more radical measures inaugurated. Quite the contrary seems to be the experience and practice of most surgeons when confronted with similar conditions. And so we naturally arrived at a consideration of the crux of the case. Here the attempt has been made to draw the picture, vividly yet impartially, and to permit the formation of individual opinion, but it seems possible to venture the assertion that jugular ligation and not jugular resection was both the operation of election and necessity. Indeed, it would seem possible to go a step further and affirm, with a fair degree of safety, that ligation is *the* operation in this type of case; avoiding as it does the increased shock and manhandling of the adjacent tissues (amounting in some instances to an avulsion), coincident with the resection of this important vessel from clavicle to foramen. Having demonstrated by inspection the condition of the visible avenues of entrance to the systemic circulation, prompt mechanical *isolation* with thorough drainage and a reliance on an aseptic petrosal clot would seem to be the chief allies to nature in the struggle these little patients must make toward ultimate recovery.

616 Madison Avenue.

A CASE OF CHYLANGIOMATA.

By C. P. FARNSWORTH, M.D.,

AND

W. T. LINDSAY, M.D.,

CHAMBERLAIN, S. D.

We wish to report a case of chylangiomata which occurred in a boy seven years of age which was interesting to us, as it baffled all diagnosis before the exploratory incision was made and because afterward we were able to find the report of only a few cases similar to this. There were about four large cysts as described in the report which contained a large amount of chyle and in our opinion would be classed as chylangiomata, or cysts formed by an enormous dilatation of lacteals in the mesentery of the bowel. We were prevented from making a post-mortem examination by the parents, so a complete pathological report could not be obtained.

This child had a prominent abdomen ever since birth, which was attributed to rachitic tendencies. The rachitic symptoms disappeared with the exception of the prominence of the abdomen. At times the child had complained of pain in the abdomen with more or less vomiting, which was attributed by the parents to bilious attacks. These symptoms would abate after a thorough catharsis. During one of these attacks, which was more severe than usual, the parents brought the child to the Chamberlain Sanitarium. Examination showed the presence of fluid in the abdomen with the accumulation of a large amount of gas. Symptoms of intestinal obstruction rapidly developed with the usual vomiting and paroxysmal pain, and though the large bowel was easily emptied by enema, there was no relief of the obstructive symptoms. A laparotomy was advised and the child was operated upon after the usual preparation. A median incision was made below the navel, when quite a quantity of ascitic fluid escaped. Four large cysts were located at the junction of the jejunum with the ilium, causing a complete obstruction of the bowel at that point by torsion. These cysts were located at the mesenteric attachment of the bowel extending down on the mesentery, and so large as to cover the bowel on all sides except the portion distal from the mesenteric attachment. They were intercommunicative as a trocar inserted into the largest evacuated the whole amount.

The bowel was then relieved of its tension by drawing off the contents through a trocar. The wounds in the bowel and also in the cyst were closed. The child lived forty-five hours after the operation. About four hours before he died a thorough normal bowel movement was obtained. The temperature did not rise above 99° or fall below 98°. The heart rapidly became weak with no apparent cause and refused to respond to stimulation, and the boy died in coma. The kidneys acted normally, but there was a slight bronchitis following the operation.

The analysis of the fluid by Dr. H. L. Peterson was as follows: Amount 3,150 c.c.; color, milky, no odor; albumin precipitated at 85° C. Microscopic examination showed many fat cells, a few leucocytes, and a few blood cells. A stained specimen showed fibrin and a few small mononuclear leucocytes. The chemical analysis showed the following: Reaction, slightly alkaline; specific gravity, 1.010; total solids, 23.30 grams; albumin, 1.5 per cent.; alcoholic extracts, 0.2925 gram; chloroform fat extracts, 2.4 per cent; etherial fat extracts, 0.0743 gram; lecethin present in moderate amount; nitrogen, 0.418 grams.

Chamberlain Sanitarium.

STRANGULATION OF UTERINE FIBROID BY TORSION OF THE PEDICLE.

By FORBES R. McCREERY, M.D.,

NEW YORK.

In *The Lancet* for July 15, 1911, there is an article by Charles A. Morton, F.R.C.S., entitled "Torsion of the Pedicle of a Uterine Fibroid," in which the author speaks of the condition as uncommon, occurring only seven times among 3,561 cases collected by Stephen Tracy in 1908. As the condition appears to be unusual, I offer the report of the following case:

Miss D., age 26. Seen October 9, 1909. Two days before she had been suddenly attacked by severe abdominal pain and vomiting. Examination

showed a large, hard, tender mass filling the lower abdomen and extending above the umbilicus. Similar masses were felt in both anterior and posterior fornices. Temperature, 99.6°; pulse, 110. Diagnosis: uterine fibroid, which had undergone inflammatory changes from unknown cause. Operation advised. On October 12 the patient was still vomiting, less pain, temperature, 99.8°.

On October 13 I opened the abdomen through the left rectus. A large, hard, dark mass presented, which was readily delivered out of the abdomen and found to be attached by a slender pedicle to the fundus of the uterus. The pedicle was twisted and the mass appeared to be hemorrhagic from strangulation. The pedicle was ligated. The entire uterus was so studded with smaller fibroids that it was removed together with the tubes and one ovary. The patient stood the operation well, but on the 19th developed a left femoral thrombophlibetis from which she made a satisfactory recovery. When last seen a few months ago she reported herself as well.

Incision through the pedunculated tumor showed it to be a fibroid everywhere congested and mottled with hemorrhagic infarcts. The tubes and ovary were normal.

123 East Fortieth Street.

Symptoms of Graves' Disease as a Sign of Tuberculosis.—F. Bialokur alludes to the frequency of the symptoms of Graves' disease as a sign of pulmonary tuberculosis. In his sanatorium in the course of one year he observed twenty-seven such instances among 330 cases. He believes that Graves' disease is often a sign of both latent and open tuberculosis, and the treatment of the former has a favorable influence upon the latter.—*Zeitschrift für Tuberkulose.*

Disorders of Nutrition.—Marcel Labbé says that nutrition is the sum of the processes of assimilation and disassimilation which take place in the animal in process of its cellular life. Nutrition has a triple end: to maintain fixed the composition of the living tissues and repair their daily waste; to maintain a constant body temperature; to produce the necessary energy for the labor of the individual. In the growing child and the pregnant woman and the nursing mother it must furnish material for tissue growth. In convalescence there is a supplementary need, the tissues must be repaired and the daily destruction replaced. The body is composed of 90 albumin, 210 fats, 590 water, 50 salts, and 60 connective tissue, making up 1,000 parts. This composition indicates the materials that must be introduced in the food to meet the needs of the body. The substances eliminated by the urine are more in relation with the ingesta than with the cellular destruction, and consist of burned materials used by the organism. The cellular waste is small. Albumins alone are not sufficient for the body; some fats and carbohydrates are necessary to maintain the composition of the tissues. Mineral salts are introduced in the fluids, and water by the various drinks. To establish the dose of different foods we estimate their value in calories. The food materials must be transformed and absorbed by the digestive tube; they must pass into the blood and so to all the tissues; and the useless portions must be eliminated. The albumins are absorbed as acid amines, the fats as soaps, and the carbohydrates as glycose. Absorbed by the capillaries the water and salts pass at once into the circulation; the albuminoids are decomposed into urea, uric acid, ammonia, etc.; the carbohydrates are held by the liver. Three great organs play a part in nutrition: the pancreas, small intestine, and liver.—*Le Progrès Médical.*

Electrical Treatment of Fibroma and Fibromyoma of the Uterus.—A. Moutier claims that there are cases of fibroma and fibromyoma of the uterus in which operation is unnecessary because one can get a symptomatic cure and reduction of the tumor by the application of a rhythmically interrupted continuous current. This application is used three times a week for ten or fifteen minutes with a strength of 15 to 60 milliampères. It stops pains and hemorrhages and reduces the size of the growth; it is perfectly harmless and should be tried always before operation. The shock and pain of the application are slight. When there is danger of malignant degeneration, dangerous compression of the viscera or great size, operation becomes necessary. This method has no chemocaustic action and is perfectly harmless; no electrolysis is made and no eschar is produced.—*Gazette de Gynécologie.*

Tuberculosis and the Tonsils.—Francesco Lasagna has made various researches with reference to the penetration of tuberculosis into the lungs through the tonsils. He injected the tonsils in cadavers, made experimental injections into rabbits, and examined the tonsils in 95 cases of death from tuberculosis. From the injections in the cadaver he concludes that the course of the lymphatics from the tonsils and from the upper air passages in general does not reach the thoracic organs, but enters directly into the large lymphatic trunks. From the examinations of tonsils from those who died of tuberculosis it resulted that pulmonary tuberculosis exists frequently with secondary tonsillar affections, that tonsillar tuberculosis is rare with intestinal tuberculosis, and that bacilli of tuberculosis and infections of the tonsils exist, accompanying specific affections of the various organs. From experimental injections in animals he showed that tubercle bacilli injected into the tonsils cause local lesions, diffusions into the lungs and intestines by inhalation and swallowing of bacilli. Tuberculosis of the tonsils is transported by the lymphatics to the glands of the neck but does not pass from these into the thorax. The final conclusions of the author are that the respiratory organs are a method of entrance for the bacilli into the lungs only by the circulation; only very rarely do the bacilli penetrate to the bronchial glands from the cervical glands.—*Archivio per le Scienze Mediche.*

The Internal Secretion of the Ovary.—Sauvé gives the structure and function of the ovary as double; the corpora lutea, organized on the type of the vascular glands, preside over the functions of menstruation and of conception; it causes the increase of the muscular and mucous tissues of the uterus in pregnancy, and for this reason in ectopic pregnancy the development of the uterus goes on for two and a half months. From the corpora lutea by injections in rabbits a serum has been obtained which immunizes against conception. The interstitial portion of the ovary with its cells acts upon all parts of the general system. It acts favorably on the formation of bony tissue, assists in the regulation of the circulation, the mass and hemoglobin content of the blood, increases the secretion of milk, the uninary secretion, the gaseous exchanges in the lungs, and the desire for nutrition, and maintains the equilibrium of the nervous system. Its removal brings about a menopause that is little different from the natural menopause, and that does not destroy the sexual instinct, but, on the contrary, in some cases increases it. There are few severe cases of ovarian insufficiency. To treat this condition there are three means: ovarian therapy, ovarian conservation, and grafting. Ovarian therapy is inadequate; ovarian conservation is at present seldom attempted; ovarian grafting is in its infancy and should be more frequently attempted. It has no bad effects that are important.—*La Riforma Medica.*

THE TURN OF THE TIDE.

EVERY dog, it is said, has his day, and to-day there are well-defined signs that even the teachers in the technical schools, including those of medicine, are about to have theirs. Those of us who live most of our time in the great American cities, and those others of us who are infected thereby from afar, sometimes never stop to realize that our accustomed gait is the pace that kills and one artificially stimulated beyond the age-long world-wide standard of normal human effort. We need occasional visits to communities where this city life of ours is seen from a greater height and therefore more broadly, for then we should sooner or later feel that the race is not indeed always to the swift nor the battle to the strong. The hustle and bustle and rustle are not always nor everywhere worth while, "for life is deeper than we think who fret along its shallow bars." The frank and well-informed individual realizes among other things that the craze for scientific research, over all obstacles, at any and every cost, financial or personal, is part of this unseemly scramble after many things that we can do almost as well without. This philosophy and this argument are obviously at their weakest when applied to human health and human life, but even then, so complex are the conditions and so uncertain, these considerations must have no little weight with many minds advanced beyond the age of thirty. Still, only one class, one kind of interest, has reason to have any real quarrel with the monomaniac researcher, for after all his efforts are wholly "to the good," save to the teaching interests, practical pedagogy, in the universities and technical schools, the seeker does no harm and often splendid good.

So much has been talked and written in praise of scientific research in the last twenty years and more, so glorious has been its apotheosis, so continually has it been dinned into our ears by certain magazine editors in season and out, vacation and term time, that the only possible ideal worthy the educated man is "original research," that, as so often happens, many who in their hearts know better have actually come to believe this and to preach it and even to live it to the exclusion of all other interests, social, family, and personal. But the advancement and the happiness of this great world of teeming millions of men need other things besides this, and above all else to-day, as in the fourteenth century buried in the dark, it needs widespread and accurate *knowledge*—for, in addition to being power, knowledge is health, long life, and happiness. The origin of this particular secular dogma we need not here attempt to trace, nor pause to describe its rise to influence; there is pride behind it and vanity and a degree of sophistry that strives to "make the worse appear the better reason." Obviously the large development of the graduate schools in the great universities has had something especially to do with it, and the avalanche of doctorates in philosophy, each crying forth for more worlds to conquer—in order to the fixation of a "job." This particular phase of the matter obviously is of German origin, tonic certainly, but, as the old pun runs, too tonic for a life-long rule for the multitude.

But, as we set out by saying, now the pendulum seems to be swinging, and ever faster, the other way, back to a recognition of the obligation of teaching institutions to *teach*, and that as well as they can. Trustees and college presidents and medical deans are gradually becoming better and better aware of something they really knew all the while, namely, that the advancement of learning depends in part on other factors than original research carried on by specialists as their life pursuit. The governors of the medical schools are beginning to realize, in fine, that the public benefit may be promoted as much by *extensive* knowledge and reason as by *intensive* learning—that to instruct ably many potentially productive minds helps in the evolution of useful science at least as much as to train and support a few whose actual "contributions" are always problematic and uncertain, however continuous.

How easy it would be were it not so ungracious a task to point out striking cases of years of research by men who draw large and life-long salaries, practically wasted if we look far enough ahead—and sometimes not so far after all! We often hear it explained in extenuation of this waste of time and talent that no man can say what apparently insignificant research may not in the future prove the indispensable link in an important chain, and allowance must be made always for this possibility. But, in opposition, no man can tell us either what raw, strong-minded youth reared on the wholesome back-farm along the Nova Scotia coast, stimulated by the best efforts of some talented teacher in some medical school, may not become another Pasteur and put them all to shame! The factor of "chance" in human nature's genius and scientific productiveness has been too little considered often times by the city-born proud wielders of scientific reputation. The typical seeker after new truth seldom reaches these new personalities to spur them on, yet these in the long run are the force and material by which the world gets on. They need first of all to be well taught, and in being well taught are included both "leading out" (education) and the highest sort of stimulation (inspiration). These can come only from the best men, men not only with learning, deep and broad, but with personality, and, moreover, with a consciousness of the supremacy of their privilege as teachers.

Meanwhile the medical schools, like the others of the technical class, suffer very generally from a lack of competent instructors. The chief aim in many colleges seems to be to employ men (who are meanwhile the only teachers) who are eminent for what they have discovered, often early in life for once, and, as all research men know so well, often by merest chance that favored them above their fellows. In the pursuit of original research the famous "man behind the gun" is not by any means the whole thing concerned. Research, of course, is commendable and constitutes one of the noblest of vocations or avocations, but it does seem that it should be done on a foundation entirely independent, financially at least, of the routine instruction in the medical schools. Its proper place, seemingly, is in institutes of research which to any desirable number might be supported almost by the interest on the interest of many of the great fortunes of this land. There is an ever-more urgent demand for skilled medical instruction that will raise the learning and the enthusiasm of the medical student into its proper elevated place. The aim of the medical schools, in short, should be to employ teachers as skilled pedagogically as can be found. Seldom indeed are such men newspaper heroes of discovery, yet no profession is nobler or more useful than theirs.

STATISTICS OF TUBERCULOSIS.

While in no way desiring to belittle the efforts of the enthusiasts in their laudable endeavors to check the ravages due to tuberculosis, it is difficult to resist the conclusion that the marked decrease in the death rate from this disease is probably to be attributed more to natural agencies than to human efforts. In the monthly bulletin of the New York State Board of Health for March of the present year it is stated that the deaths from consumption have fallen from 205 per 100,000 in 1890 to 158 per 100,000 in 1910. These figures apply to the whole State. It would be pertinent to inquire what was the rate of decrease before this time. In an article published in the *Journal of the American Medical Association,* October 20, 1900, Guy Hinsdale graphically showed that in the city of Philadelphia, from 1870 to 1897, there was a constant, regular decrease in the yearly death rate from tuberculosis. In the period from 1885 to 1900 it fell from 14 per cent. of all deaths to 10 per cent., but in the year 1899 there was an increase over the preceding year. It would seem only fair to infer that in a disease whose average natural course extends over a period of several years any sudden decrease in the death rate extending over a period of two or three years should not be hastily ascribed to any special prophylactic measures any more than should a sudden increase to the lack of them.

The majority of the statistical studies of this subject have been made by physicians who, as a rule, have received no special training in the interpretation of figures. The time is now ripe for a study of the data at hand by men who are trained statisticians and who have no interest or prejudices one way or the other in regard to the disease itself. So far, the most important work in this line is probably that of Karl Pearson in England, in 1907. His study was based upon the absolutely complete family records of 384 stocks or families in which tuberculosis had occurred. He reaches the conclusion that the tuberculous diathesis is certainly inherited, and that the intensity of its inheritance is sensibly the same as that of any other physical character as yet investigated by man. Although infection plays a necessary part he determined that it was secondary to that of inheritance in the families investigated. He considers it doubtful if the risk of infection can be escaped except by the absence of the diathesis; that is, by the inheritance of what amounts to the counter-disposition. The average age of onset was found to be 29 years in males and 25 years in females. The children of tuberculous family history who became infected suffered this infection at an earlier average age than those who became infected in non-tuberculous families. This earlier age infection, Pearson thinks, cannot be properly attributed to infection from the other members of the family, because the bulk of the parents must have passed the danger zone before the children had reached the average age of onset; and, moreover, in the laboring class, from which these statistics were compiled, many of the children must have already left the immediate home environment. The earlier age of onset in the children is probably associated with the same tendency to earlier inheritance noted in cases of cancer and defective vision, where the question of infection hardly arises. He further concludes that, strange as it may seem from the statistical standpoint, the marriage of the actually tuberculous is less productive of evil than the marriage of those of the tuberculous stock, for the actually tuberculous have a shorter period of time in which to propagate, consequently the children will be fewer in number, and this, taken in conjunction with the fact that these children will have a tendency to become infected at an average earlier age than the usual average age of onset, tends to the self-destruction of the actually infected stock.

The statement of Professor Willcox, the consulting statistician of the New York State Health Department (Report on Vital Statistics, August, 1910), that, "no influence of the special campaign against tuberculosis can be traced in the [mortality] figures," would seem to be entirely consistent with the general conclusions of Pearson. It is in accord also with the conclusion of Maher of New Haven (Medical Record, August 1, 1908) that "there has been a very marked decline in the tuberculosis death rate for the past fifty years, and this decline was as steep, but not as regular, before the discovery of the tubercle bacillus as it has been since."

SURGICAL TREATMENT OF NEPHRITIS.

When early in 1899 the late George M. Edebohls announced his observation of striking improvement following decapsulation of the kidney in cases of chronic nephritis the first tendency was to credit surgery with another great victory over the medical treatment of this disease. Since that time hundreds of patients have undergone the operation in ques-

tion, and the early enthusiasm has given place to an almost equally emphatic disapproval of the procedure in most medical circles. That this, however, is but the usual swing of the pendulum and that the operation has its well-defined indications is the theme of an interesting paper by Morris Booth Miller in the September number of the *American Journal of the Medical Sciences*. Miller shows conclusively that Edebohls' idea of the salutary changes produced by the decapsulation of the kidney cannot be accepted. New blood supply arising from the perinephritic areas and rejuvenating the diseased kidneys has only a theoretical existence. Reis examined six hundred denuded kidneys to find in one only evidence of a new blood supply, while the well known proneness of perinephritic tissues to suppuration depends upon their poor provision with arteries, which can hardly be expected to feed the kidneys in addition.

Yet there is no question that in many instances striking relief of symptoms that occasionally even threatened life were obtained by Edebohls and other surgeons. Still more to the point has been some of the experimental evidence offered. Rovighi found that in cases of cantharides-nephritis in rabbits all recovered after operation, while 50 per cent. of the controls died; in diphtheria-toxin nephritis 50 per cent. were saved by decapsulation, while 100 per cent. of the control animals died.

Long before Edebohls began to advocate boldly his operation, Harrison of London noted the amelioration of nephritic symptoms in patients upon whom nephrotomy was done for supposed calculus or other reasons. He thought that the changes in tension and the diminution of congestion of the kidneys were to be credited with the salutary effects, and Miller is disposed to accept this view. Decapsulation accomplishes all that the time-honored cupping and blood-letting, both admittedly helpful, can accomplish, and much more thoroughly and directly, as it acts at the very focal point of the disease. This is why the best results have been obtained in cases accompanied by hypertension of acute onset and those showing much edema within the kidney itself.

Miller concludes that the operation should be given a well-defined place in the treatment of nephritis. It may be hopefully done in acute forms of the disease, young patients being the best subjects. There exist sound reasons for operating for anuria or uremia occurring in chronic nephritis; but in any case the operation should be done only after medical treatment has failed. As a last desperate chance, however, it may be done in any form of nephritis.

The Pasteur Treatment of Rabies.

In the report of Jules Viala of the Pasteur Institute in Paris for 1910 (Annales de l'Institut Pasteur. Tome xxv, No. 7, p. 558) is found a forceful reply to that class of our populace which decries the Pasteur treatment as a danger, and productive of more cases of rabies than it cures. During the year 1910, 401 persons received this treatment without a single death resulting from any cause. This remarkable record is probably due in part to the greater popular appreciation of the value of the treatment in Europe so that the Institute is not called upon to treat patients in whom the disease is so far advanced that a fatal issue is certain. The report is, however, no less an impressive demonstration of the care with which the treatment is administered and its harmlessnes to the healthy person. A record of 401 successive series of inoculations without accident is strong witness to the ability of those using the method. During the past ten years 7,380 persons have been treated of whom only 21 have died from all causes, a mortality of 0.28 per cent. The report is altogether a most convincing argument except to those "who having eyes see not and having ears do not hear."

News of the Week.

Low Infant Death Rate.—For the week ending September 23 there were 324 deaths of infants under one year of age in New York, as compared with 343 for the same week in 1910. The total number of infant deaths so far this year is 11,442, as compared with 12,603 for the same period in 1910, a decrease of 1,161.

Pure Food Fight.—President Seth Low of the National Civic Federation has issued a call for two meetings of the Pure Food and Drug Department of the federation. Both meetings will be held in the rooms of the New York Board of Trade on October 2. At these meetings the department will determine upon a line of action after taking up the following questions: "What is the actual situation in this country with reference to the enforcement of the Federal and State pure food and drug laws?" and "What legislation and what changes in administration will more effectually safeguard the people against alleged food and drug adulterators, misbranders, and short weighers?" Among the announced speakers are Dr. Harvey W. Wiley, Dr. Thomas Darlington, and Dr. William C. Woodward, Secretary of the American Public Health Association.

Ban on the Public Drinking Cup.—Police Commissioner Waldo of New York City recently made public the Police Department circular which deals with the law prohibiting public drinking cups after October 1, 1911. The paper reads: The use of a common drinking cup for drinking water in any public place, or in any public institution, hotel, theater, factory, public hall, or public school, or in any railroad station or ferry house in the City of New York, or the furnishing of such a common drinking cup for use in any of such places, is hereby prohibited."

New University Department.—Princeton University opened on September 21 with a newly created department, that of hygiene and physical education, under the charge of Dr. Joseph E. Raycroft, formerly of Chicago.

New Cancer Hospital.—Plans for the new building for St. Rose's Free Home for Incurable Cancer, to be located opposite Corlears Hook Park, New York, call for a five-story building of brick with terra cotta trimmings. A chapel will occupy the top floors, and there will be a large reception ward and a number of private rooms, sun parlors, etc. The cost is estimated at $100,000.

Columbia University and the Presbyterian Hospital.—An article in a recent issue of the *New York Times*, evidently intended to convey the impression that some hitch had occurred in the

working out of the alliance between the College of Physicians and Surgeons, Columbia University, and the Presbyterian Hospital, was promptly answered by a letter from President Sturges and Vice-President De Forest of the hospital, who stated emphatically that there was no lack of accord between the officials of the two institutions, that the hospital managers were in perfect agreement as to the alliance, and that the erection of new buildings on the site selected by the late Mr. Kennedey at Avenue A and Sixty-seventh street was the ultimate intention. The scope of the hospital work has been broadened by the alliance, and the requirements for the new buildings have increased so that great deliberation in the preparation of the plans is necessary, and these are now being made the subject of careful study by the members of the building committee.

A Serum Farm in Ohio.—Plans for the immense Ohio State serum farm, the first of its kind in the United States, have recently been made public. The farm, which consists of ninety acres of land in Licking County, Ohio, was purchased by the State two years ago, and on the property it is now proposed to erect ten buildings, including laboratories, etc., in which the work of the institution will be carried on. The Legislature has already made an appropriation of $60,000 for the purpose. The progress and work of this innovation in medical work will be watched with interest throughout the country.

Gifts to Charities.—The will of the late John W. Gates, who died in Paris recently, contained only one public bequest, that of $100,000 to the Mary G. Gates Hospital at Port Arthur, Texas.

An Aged Indian.—Mrs. Sala Plummer, the oldest member of the Seneca Indian tribe, died at her home near Jimmerstown, N. Y., on September 18, at the age of 108 years.

Shaker Held for Murder.—After an investigation of the circumstances surrounding the death of a member of a Shaker colony in Florida, who was chloroformed by her coreligionists, the coroner's jury returned a verdict charging the head of the colony with murder. The autopsy showed that the woman's lungs were only slightly affected and that she was otherwise in good physical condition. The members of the colony had announced that the chloroform was administered at her own pleading to end her sufferings from tuberculosis.

University Isolation Hospital.—The trustees of Leland Stanford University, California, have finally selected a site for an isolation hospital for the university, the site consisting of two and a half acres of land near Felt Lake and about two miles from the university buildings.

Typhoid Epidemic.—An outbreak of typhoid fever at Torrington, Conn., is causing some concern. Up to September 23 two cases had been reported with five deaths.

Vital Statistics for Connecticut.—During the month of August there were 1,421 deaths in the State, 127 less than the average for August for the five years preceding. The death rate for the large towns was 14.3, for the small towns, 14.8, and for the whole State 14.4. The deaths from infectious diseases numbered 170, or 11.9 per cent. of the total mortality.

Cholera in Italy.—The official reports of the cholera situation in Italy indicate a slight decrease in the number of cases. From September 10 to 17, inclusive, there were 1,007 cases and 320 deaths. For the first time the disease has been reported in Sardinia, fifty-four cases and nineteen cases having occurred.

Hartford Baby Hospital.—The summer hospital for babies in Hartford, Conn., closed its fifth and most successful season on September 15.

War on Hookworm.—The California State Board of Health has requested the co-operation of the Public Health and Marine-Hospital Service in an investigation into the prevalence of hookworm infection throughout the State. Recent work of the immigration service has shown that upwards of 25 per cent. of immigrants entering the State are infected, and it has also developed that many of the State's deep gold miners are suffering from the disease. Dr. Charles W. Stiles of the Public Health Service is now engaged in investigating conditions in Texas.

Washington County (Vt.) Medical Society.—At the annual meeting held in Barre on September 12, the following officers were elected for the ensuing year: *President,* Dr. C. E. Chandler of Montpelier; *Vice-President,* Dr. C. J. Rumrill of Randolph; *Secretary,* Dr. E. A. Colton; *Treasurer,* Dr. L. A. Russlow of Randolph.

Obituary Notes.—Dr. George R. Vernon died at Clifton Heights, Pa., on September 16 at the age of 64 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1875.

Dr. William Flynn of Marion, Ind., a graduate of the Louisville Medical College, Kentucky, and a member of the American Medical Association and of the Indiana State and Grant County Medical Societies, died at his home of cerebral hemorrhage, on September 2, aged 61 years.

Dr. Eugene F. Rink of Burlington, N. J., a graduate of the Hahnemann Medical College of Philadelphia in 1877, died at his home after a long illness, on September 7, aged 60 years.

Dr. Granville W. Tinkham of Weymouth, Mass., a graduate of the Harvard University Medical School in 1871, and a member of the Massachusetts Medical Society and of the South Norfolk Medical Society, of which he was an ex-president, died in the Boothby Hospital, Boston, on September 10, aged 63 years.

Dr. Jacob Weber of Philadelphia died at his summer home at Cape May, N. J., on August 29, at the age of 64 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1858.

Dr. William F. Roth died at Manheim, Pa., on September 4, at the age of 40 years. He was graduated from Hahnemann Medical College of Philadelphia in the class of 1894.

Dr. Robert N. C. Tate of Gonzales, Tex., a graduate of the Medical Department of New York University in 1849, and a member of the Texas State and Gonzales County Medical Societies, died at his home after a long illness, on September 4, aged 84 years.

Dr. Thomas R. Ward of Omaha, Neb., a graduate of the State University of Iowa College of Medicine in 1873, and of the Bellevue Hospital Medical College, New York, in 1882, and surgeon to the Swedish Hospital and Training School for Nurses, Omaha, died at his home on September 9.

Dr. Henry Herbert Herbst of Allentown, Pa., died at Philadelphia on September 20 at the age of 53 years. He was graduated from the medical department of the University of Pennsylvania in the

class of 1881. For a year after graduation Dr. Herbst was examining surgeon for the Pennsylvania Railroad at Wilmington, Del. Subsequently he returned to Allentown to engage in general practice. For two years he was Coroner's Physician and City Physician for the Poor Directors, and he was President of the local Board of Health from 1890 to 1895. From 1888 to 1897 he served on the United States Board of Pension Examiners. He was president of the medical section and first vice-president of the Medical Society of the State of Pennsylvania in 1909. In 1908 he was elected Mayor of Allentown by City Council. He was at one time one of the physicians to the Allentown Hospital, and also professor of physical education in Muhlenberg College for fourteen years.

Dr. Walter Scott Holliday of Hamilton, Ala., died at his home on September 8, aged 69 years.

Dr. George D. Towne of Manchester, N. H., a graduate of Dartmouth College in 1875, and of the Medical Department of New York University in 1878, and a member of the New Hampshire State Medical Society, and of the Surgical Club of New Hampshire, died at his summer home in Dunbarton on September 11, aged 57 years.

Dr. Luther M. Zimmerman of Hagerstown, Md., a graduate of the University of Maryland School of Medicine in 1864, died at his home on September 13, aged 71 years.

Dr. Archibald A. Strange of Burkesville, Ky., a graduate of the University of Louisville Medical Department in 1889 and a member of the Kentucky State and Cumberland County Medical Societies, died at his home on September 11, aged 70 years.

Dr. William Lorenzo Goodale of Montpelier, Vt., a graduate of the Medical Department of the University of Vermont in 1888, died in the Heaton Hospital of cerebral embolism on September 17, aged 44 years.

The Thirteenth Annual Conference of the American Hospital Association.

The annual conference of the American Hospital Association was held in Murray Hill Hotel, New York, on September 19, 20, 21, and 22. The opening address was given by the president, Dr. Warren L. Babcock, superintendent of the Grace Hospital, Detroit, Mich. After alluding to the progress made by the association since its inception as, for example, in the production of hospital literature of its own, in the development of hospital training schools, in the advance in hospital construction, in which advance the association had played its part, the speaker went on to sketch the rôle of the association in the future. He pointed out that in specialism and broad generalization the immediate cure of illness is but one of the functions of hospitals, and the progress of the work of the association in the future will bear out the statement that the campaign for the prevention of disease, the teaching of the ordinary rules of hygiene to the public, the instruction of mothers in the care of infants, and the wiping out of infectious and contagious diseases will be part of the work of superintendents and others connected with hospitals. The hospital engaging to teach medicine in connection with a medical school should be an adjunct to a university. The need for the thorough training of hospital superintendents was emphasized, and finally the necessity for efforts by the association toward the standardization of work in all departments was insisted upon.

The secretary of the association, Dr. I. N. G. Brown of Toronto, read a paper giving his impression of a trip to Europe, during which he occupied his time in visiting hospitals in Great Britain, Germany, France, and Austria. He pointed out that Great Britain was the only country in Europe in which the hospitals with few exceptions are supported by charity, while on the Continent hospitals depend on the public purse for their maintenance. In America, excepting in parts of Canada and in Pennsylvania, few hospitals receive State aid. Dr. Brown was of the opinion that the European plan was better. In the large teaching hospitals of Germany not only does the State supply a full equipment for the care of the sick, but also for the training of medical students. The result is seen in commodious and well-equipped laboratories for chemical, physical, and bacteriological investigations. Moreover, there is also a full staff of assistants at the command of the investigator, the teacher, and the professor. With respect to hospital administration, the speaker was of the opinion that a medical man, *ceteris paribus*, is the best kind of director of a large hospital, but, if he is appointed to fill such a position he should be relieved of work which belongs to the medical staff. Furthermore, Dr. Brown believed that a hospital, large or small, should have but one head, and that the work of that head in a large hospital should be administrative only. Medical organization differs considerably in the United States and Great Britain from that in vogue in the hospitals of Europe. In European hospitals members of the visiting staff are servants of the State, they are paid for their services, and frequently move from one hospital and teaching center to another. As to hospital construction Dr. Brown believed that Europe is ahead of this country and of Great Britain, and he was particularly struck with the bath-house and disinfection building features of all large hospitals in Europe. With regard to ventilation the speaker observed that in European as in American hospitals the modes of ventilation were numerous, but he held the view that the more elaborate systems do not give so satisfactory results as the simpler, a view shared by perhaps the great majority of authorities on the subject. The next paper read was upon the same subject, the author being Mr. Edward F. Stevens of Boston, Mass., a traveling companion of Dr. Brown on his European tour. Mr. Stevens, who is an architect, dealt with details and equipment of the hospital, comparing the hospitals on the other side of the Atlantic with those on this continent from this point of view. The interest in this paper was greatly enhanced by the fact that the points were exemplified by illustrations on the screen from photographs taken by Mr. Stevens himself.

Mr. J. M. Cosgrove, manager of the Winnipeg General Hospital, read a paper in which he stated that until antityphoid vaccine came into use it had been almost impossible to prevent the spread of typhoid fever among nurses. In the discussion which followed, Dr. H. W. Austin of the United States Public Health and Marine-Hospital Service said the vaccine treatment for the prevention of typhoid fever was being more and more used in the marine hospitals, and with success. He thought it the best preventive of typhoid fever as yet introduced. Dr. Morrell of Baltimore related how effective its employment had been in the army camps at San Antonio, and stated that among 1,200 men who

submitted to the treatment but one had the disease, and in his case the attack was mild.

Mr. Robert W. Hebberd, secretary of the New York State Board of Charities, made somewhat severe reflections on the lack of hospital facilities in New York City. He declared that the city was a generation behind many other cities in public hospital and ambulance service. A paper was read on hospital social service by Miss Mary E. Wadley of New York, and in the after-discussion Miss Louise C. Brent, superintendent of the Hospital for Sick Children, Toronto, made some apt remarks on this question of rapidly increasing interest.

With regard to hospital organization in relation to education and research, Mr. Abraham Flexner had much to say. He said twenty small medical schools had closed their doors during the past year, a result due, he asserted, to the campaign undertaken against the hospitals that permitted them to flourish. He said that the main supporters of these medical schools are the hospitals in their respective towns, which permit the students to glean what knowledge they may from the institutions. According to Flexner, in many instances this assistance is given grudgingly. He thought if it were withdrawn altogether the result would be for the betterment of the profession. "Before the hospital opens its wards to educational uses," said the speaker, "it not only may but must satisfy itself that the medical school applying for its privileges has in the first place enrolled a competent student body, that it has provided adequate facilities for instruction in the underlying medical sciences, both in the way of laboratories and teaching staff, and that it is prepared to take upon itself whatsoever financial obligations are incurred by introducing teaching and research into hospital wards." Flexner then named several medical schools which he thought ought to be closed. At the end of the discussion of this paper Miss Margaret Englehart, president of the Association of the Frances E. Willard Hospital of Chicago, disputed the accuracy of Flexner's strictures on certain medical schools. She asserted that at least one medical school named by him to her knowledge produces as fine a student body as can be desired, and that any graduate of that school would be welcome on the staff of the hospital represented by her.

At the closing session of the meeting the Rev. A. S. Kavanagh, superintendent of the Brooklyn Methodist Episcopal Hospital, embraced the opportunity, when reading a report of the committee on hospital efficiency, hospital finances, and economics of administration, to praise the work of Dr. Doty, Health Officer of the Port of New York. Mr. Kavanagh said: "The finest achievement of the year has been the splendid and successful fight of Dr. Doty and his assistants against cholera, which threatened the city a few months ago. Every citizen who read this story felt a sense of pride, and for the humiliating investigation to which the doctor was subjected we can only feel a sense of shame. Our investigations for the public good must not degenerate into mere political attacks." Following the meeting, many of the delegates paid a visit to the Quarantine Station and saw for themselves the excellent conditions described by Mr. Kavanagh.

The officers elected for the ensuing year were as follows: *President*, Dr. Henry M. Hurd of the Johns Hopkins Hospital, Baltimore; *Vice-Presidents*, Dr. A. J. Ranney of the Lakeside Hospital, Cleveland, Dr. J. L. Judson of the Harper Hospital, Detroit, and Miss Nancy P. Ellicott of the Rockefeller Hospital, New York; *Secretary*, Dr. J. N. E. Brown of Toronto; *Treasurer*, Dr. Asa Bacon of the Presbyterian Hospital, Chicago.

Obituary.

JAMES C. HEPBURN, M.D., LL.D.,

EAST ORANGE, N. J.

Dr. James C. Hepburn of East Orange, N. J., the oldest alumnus of Princeton University, and a pioneer medical missionary in China and Japan, died at his home on September 21, aged ninety-six years. Dr. Hepburn was graduated from Princeton in 1832, and from the Medical Department of the University of Pennsylvania in 1836. Four years later he went as a medical missionary to China, where he remained for six years. After an interval of some years in New York Dr. Hepburn again took up missionary work, settling in Yokohama, where he remained for thirty-three years, retiring from active life in 1892. Dr. Hepburn compiled the first English dictionary of the Japanese language, which was published in 1867, and from 1872 until 1888 worked at a translation of the Bible in Japanese. In 1891 he published a Japanese dictionary of the Bible. Lafayette College in 1872 gave him the degree of Doctor of Laws, and in 1905 he received the same honor from his alma mater. In 1905, also, on the occasion of his ninetieth birthday, the Emperor of Japan conferred on him the decoration of the Order of the Rising Sun, in recognition of the services he had rendered to that country.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

SCIENCE CONGRESS—EXAMINATION SYSTEM—GREAT PROBLEMS OF BIOLOGY—RAINFALL—PLAGUE REPORT—INSECT CARRIERS—LEPROSY—HEAT WAVE—INFANTILE MORTALITY—OBITUARY.

London, September 8, 1911.

The Science Congress concluded its deliberations on Wednesday. As far as numbers go the meeting has been the smallest for thirty years, the total being 1,241. Yet one would have supposed Portsmouth would have been an attractive place, and the good people there were profuse in their hospitality and provision of entertainments. Some reporters indulged in lugubrious talk about the decay of the association, but, apart from numbers, the meeting was successful. Sir William Ramsay, who as president ought to know, speaking at the dinner given by the mayor, expressed that opinion emphatically, and added: "I don't think there has been any decay at all." Certainly there were interesting papers and discussions, both on the scientific and popular side, for the association embraces both, and in that holds a special position. Those who have forgotten this should be reminded that its name implies this in the words "for the advancement of science," and in the proposal for its formation in 1830 by Sir D. Brewster it was to be "an association of our nobility, gentry, clergy, and philosophers;" in fact it was to consist, not of pure scientists alone, but of all sufficiently interested in any branch of science to take part in it. This position has been maintained for

eighty-one years, during which the most eminent exponents of pure science have taken part in the proceedings. Perhaps, this year, what some have called the social side has been more represented than the technical, but there has been a good supply of papers in both. Those of strictly medical interest were not numerous, but questions cropped up in different sections which deserve brief mention.

Sir William Ramsay, the president, looked in at the Section of Educational Science during a discussion on the Plan of Examinations and made a short speech, in which he startled many of the audience and sent a thrill through the profession by saying he did not think it should be necessary for a man to pass an examination before practising medicine, if a doctor under and with whom he had worked certified that he was properly qualified so to practise. There will be plenty of objections put forth to this view, and, admitting with the president that examinations are a poor test of mental power and that they have taken too great a place in our general scheme of education, the public will hardly be willing to dispense with some security beyond an individual's certificate, and our numerous licensing bodies will agree on the necessity of their existence.

Prof. D'Arcy W. Thompson gave an address on the "Greater Problems of Biology," in which he said that to-day biologists are in no sense in an exultant mood. What above all they would like to explain baffles explanation, and the living organism is a fundamental fact. Now, as in the beginning, wonderment and admiration are the portion of the biologist as of all who contemplate the heavens and the earth, the sea and all that in them is. If wonderment, as Aristotle said, springs from seven causes, it does not cease when proximate causes are discovered. Beyond lies the final cause, the reason why in which are hidden the problems of organic harmony and autonomy, the mysteries of apparent purpose and design. Here the plain rationalism that guided us through physical facts and causes begins to disappoint us, and intuition, which is of close kin to faith, begins to make herself heard.

Dr. R. H. Mill, director of our Rainfall organization, gave a lecture intended for the operative class, but which I am told was equally attended by scientists and was very heartily appreciated by all. He described the organization he controls in popular terms and indulged in some humorous remarks, and ventured to forecast that we may be entering on a series of wet seasons after this unusually dry one.

The Local Government Board has issued the report of its investigation respecting the cases of supposed plague. The late Dr. Bulstrode took the leading part in this and was aided by the Lister Institute staff. The report is furnished with a map over which alleged human cases occurred from 1906-7 to 1910. The bodies of rats dead of plague were found in the locality, and it suggested that the epizootic had been present from the earlier date. Nevertheless only three, or at most four, cases of primary plague in the human subject can be admitted, all others being clearly secondary. This is attributed to the fact that only one variety of the fleas which infest rats seems inclined to bite man. And comparatively very few of this flea were found on the bodies of the dead rats examined. In the time of the great plague of London the black rat was abundant in this country, but some years later the brown rat arrived and eventually exterminated the native. The cases which had to be investigated on the eastern coast and which occurred in the winter 1909-10, were in number eight, and five of them were fatal. Two post-mortems were made and a suspicion that they might have been due to some form of poisoning caused great excitement in the locality. Dr. Bulstrode carried out a most careful and thorough investigation, and concluded that the cases were really plague. No other view explains all the facts collected as this does, but it seems uncertain whether the disease was bubonic or septicemic plague. Drs. Martin and Rowland of the Lister Institute contribute to the report an account of rat fleas, which will interest everyone practising in countries where plague is met with. Drs. Petrie and Macalister, also of the Institute, report on the rats which were collected and the pathological and bacteriological conditions observed in some of them. Changes in the liver and other glands were met with and in three instances a bacillus resembling *B. pestis,* but on later examination it was decided that this was of a pseudotuberculous type.

Fleas, like mosquitos and probably all blood-sucking insects, must be regarded possible carriers of disease. Dr. Sanders of Bobben Island Leper Asylum has contributed to the *South African Medical Record* of July 8 an account of experiments he has been making to determine whether leprosy may be propagated by these insects. He applied them, after confining them for a time without food, to the skin of patients. His most important result was with the bedbug, in which he found the leprosy bacillus in about 30 per cent. after such feeding, but none in controls. Not only in the stomach and intestines of the insects, but in much greater numbers in their tissues, were the bacilli found, and continued to be for sixteen days. He concludes that this species of insect is probably an important agent in spreading leprosy.

During the recent hot weather there was a sudden rise in the infantile mortality in London. At the end of July the deaths from diarrhea and enteritis under two years of age rose from 173 to 304, and toward the end of August, 635 per 1,000. Last week the number was 537. Many are blaming the heat wave, but that cannot be the direct cause, for the heat had been with us a month before the rise began. Indirectly it may be reckoned as a cause, and there is some evidence that the house fly is a carrier of infection. A great outcry is being raised in some districts where it is said swarms of flies have appeared earlier than usual. To restrain its multiplication thorough scavenging is necessary, and in some parts this has been effectually done. When the habits of this insect are considered, it is obvious that it may carry into the houses particles of the filth in which it has been exploring and laying its eggs. With filth adhering to its legs and body, it enters and explores and if not driven away walks over food, as well as everything else. We may drive it out by various fumes, but it is better to arrest the development by scavenging. It is to be hoped the present outcry will promote this sanitary measure.

The heat wave of which so much has been made has certainly been responsible for much, but it has given us the most delightful summer for many a year. Drought is admittedly a feature, but it has not been the driest season on record. In the past three months London received 3½ inches of rain, just about half our average, but 1 inch more than in 1808. But the splendid brilliancy of the summer is shown more by the records of bright sunshine. Greenwich automatic instruments registered ninety-two consecutive days of sunshine up to August 21.

July was the sunniest month with over ten hours' sunshine every day at nearly all the stations. For a spell of thirteen weeks we had two or three hours a day above the average. At Greenwich it aggregated 819 hours, or 176 above normal; at Westminster, with a total of 774, the gain was 255, equal to 50 per cent. And August does not close the record, for September is doing its best to rival it in spite of slight misty mornings, but temperatures in the eighties. Yesterday it reached 89° F., with eleven hours' bright sunshine.

Mr. Horace Nutt, M.R.C.S., 1861, said to be the last "King's" Coroner, died on the 6th inst., at 72. He had been Coroner for Sherborne and Yelminster from 1876. He had the title of King's Coroner, which carried special powers in his district, to which he was further Medical Officer of Health for many years.

Surgeon-Major A. A. Mantell, formerly of the Indian service, died on August 22 at Bath, aged 80.

Dr. Leonard Cune, formerly surgeon to the Peterborough Infirmary, has died at Eastbourne at the age of 63. He took M.B., London, 1872, and the next year M.D. and M.R.C.S.

THE GENESIS OF UTERINE CANCER.

To the Editor of the Medical Record:

Sir:—In reference to the uterine cancer research, concerning which you recently published two articles, "Uterine Cancer and Its Early Diagnosis. Original Research from Subjective Symptoms" (May 20, 1911), and "Cancer, a Suggestion as to Its Cause, and Its Relation to Displacements, Functional Disorders, and the Nervous System" (September 9, 1911), may I ask the favor that you notify your readers that interrogatory blanks are now completed for the furtherance of the research. Applications for and the prompt filling and return of these question sheets are earnestly solicited, and will be greatly appreciated.

E. Atlee, M.D.

Thoracic Surgery. J. G. Mumford.
The Treatment of Empyema. F. B. Lund.
Bronchiectasis and Abscess of the Lung. S. Robinson.
Chest Traumata. F. T. Murphy.
The Use of the Esophagoscope in Esophageal Surgery. H. P. Mosher.
Value of the Röntgen Rays in the Diagnosis and Treatment of Fractures; Moral and Legal Obligations. H. A. Lothrop.
Suits for Alleged Malpractice. G. W. Gay.

Thoracic Surgery.—J. G. Mumford states that while a differential pressure apparatus is extremely valuable, and while its use is leading constantly toward safer and surer methods of operating, nevertheless it is found that even without differential pressure the general surgeon is able to approach and to deal with disease within the thoracic cavity with increasing benefit to the patient. The lesions and diseases which fall within the surgical field are: (1) foreign bodies in the bronchi; (2) bronchiectasis; (3) empyema; (4) injuries, especially those associated with hemothorax; (5) tuberculosis; (6) pulmonary abscess; (7) pulmonary gangrene; (8) echinococcus cysts; (9) actinomycosis; and (10) tumors of the chest-wall, pleura, lungs, and esophagus.

Treatment of Empyema.—F. B. Lund describes the operation of excising a portion of a rib and draining the pleural cavity. Rib resection and very free drainage are efficient and less likely in the hands of most surgeons to be followed by accumulation of pus requiring secondary operation. The siphon methods have the advantage of ease and simplicity of performance, may be usually done under local anesthesia, and may be done without spilling pus about or even into the wound. But the former method has given the better results in the hands of the author.

Bronchiectasis and Abscess of the Lung.—S. Robinson notes that the surgery of bronchiectasis comprises two possibilities: immobilization of the lung or resection. If there is bilateral involvement, both are useless. If the involvement is diffuse in one lung, immobilization is alone indicated. If confined to one lobe, either immobilization or resection is to be considered. Immobilization consists in putting the lung at rest by collapsing it as much as adhesions will permit. This results in a reduction in the capacity of the bronchiectatic cavities and may lead to cicatrization. The conservative method of immobilization consists in the introduction of nitrogen gas into the pleural cavity, producing an artificial pneumothorax. Radical immobilization consists in an extensive resection of ribs over the infected lung. Complete resection of a bronchiectatic lobe is, theoretically at least, the indicated treatment. Acute abscess of the lung is generally a post-pneumonic process, though frequently occurring after tooth extractions and tonsil operations. Spontaneous cure by the gradual or sudden evacuation of pus by the bronchus is not of infrequent occurrence, and the patient should be given opportunity for this method of cure. The surgeon should relieve the internist of the duty of localizing suppurations. Exploration for deep abscess in the complete absence of adhesions is more safely performed under differential pressure.

Chest Traumata.—F. T. Murphy limits his remarks to penetrating wounds of the chest wall, the results of stab or gunshot wounds. Of 42 cases treated at the Massachusetts General Hospital during the past 30 years, only 4 died. The analysis of the symptoms of these cases brings out the following points: (1) The very frequent complaint of abdominal pain, even though the peritoneum was not affected. (2) The possibility of a serious hemorrhage from a wound of the intercostal artery, one case at autopsy showing this to have been the source of hemorrhage. (3) The great power of accommodation of the lungs to hemorrhage or pneumothorax, if the change comes on slowly. (4) Relatively slight danger of fatal hemorrhage because of the collapse of the lung and the adherence of the pleura.

The Esophagoscope in Esophageal Surgery.—H. P. Mosher states that there are three possible dangers in the use of the esophagoscope, namely, rupture of an aneurysm, perforation of the esophagus, and sloughing of the esophagus from pressure of the tube. The pathological conditions which are best determined by the esophagoscope are new growths and pouches, spasm of the cardia, foreign bodies in the esophagus, and corrosive strictures of the esophagus.

The X-Rays in the Diagnosis and Treatment of Fractures.—H. A. Lothrop states that it is advisable to have a skiagraph made before reduction is attempted, thus establishing an accurate diagnosis such as cannot be made by the usual clinical methods. This reduces to a minimum the amount of manipulation, which frequently increases the injury to soft parts, and, finally, permits of more intelligent replacement of parts. During the pliable period of the provisional callus the alignment can be controlled. The eye is sufficient for this control in many instances, but very frequently the skiagraph is the only means of control. If only one plate can be made the choice of time will be after the fracture has been carefully examined and reduced under a general anesthetic and the permanent apparatus applied. The skiagraph then serves for diagnosis and control. The diagnosis and treatment of dislocations and fracture-dislocations are more urgent than in the case of simple fractures, so that here again an early skiagraph is desirable.

Suits for Alleged Malpractice.—G. W. Gay states that no physician is legally obliged to respond to any call for his professional services. Having accepted service in any case, however, the law requires three things of him, to wit: "A reasonable degree of the learning and experience ordinarily possessed by the medical men of the time and neighborhood. Reasonable and ordinary care of the case committed to him. Exercise of his best judgment in cases of doubt. These promises he takes with him to every sick room."

Iritis Plastica Adhærens. A. M. WacWhinnie.
Scarlet Fever, Complicating Pregnancy, Labor, and Puerperium. S. Herzstein.

Salvarsan.—A. L. Wolbarst notes that of 150 cases of syphilis that he treated with salvarsan 74 per cent. were either cured clinically or greatly improved. He states that of the various methods of administering salvarsan the intravenous injection is by far the most agreeable from the patient's standpoint, and is probably the most effective. It should be carefully given and repeated once or twice at intervals of two or three weeks. For the sake of further security, it is well to precede and follow these injections with a course of mercurial inunctions or injections. Next to the intravenous method, the intramuscular injection of an iodipin emulsion is the most desirable, but it is still to be proved that it is as effective as the intravenous or the alkaline intramuscular method. It has the single advantage that the treatment may be given by the physician in his office, and the patient may then go home.

Gastric Contents in Gastroptosis.—T. R. Brown concludes that while in individual cases of gastroptosis one may meet with varying amounts of free hydrochloric acid, ranging from a condition of achlorhydria to one of hyperchlorhydria, nevertheless the tendency in the majority of these cases is toward a distinct diminution of the free acid. The extent of this diminution is dependent upon the amount of downward displacement of the stomach, the diminution being slight in the cases of slight descensus; very marked, with a tendency to complete disappearance, in cases where the ptosis is very great. The fact that so many of the patients with marked ptosis show a complete absence of free hydrochloric acid suggests that gastroptosis may be one, if not the most important causative factor of achylia gastrica. That this achlorhydria is functional in a large proportion of these cases is shown by the fact that under the appropriate treatment, overfeeding, a proper dietary, rest at appropriate times, the wearing of a suitable support, and postural treatment in conjunction with the administration of hydrochloric acid by mouth, there is usually a return of the free hydrochloric acid after the test meal, although it may require persistence along this line of treatment for many months before this occurs.

Duodenal Ulcer.—J. P. Crozer Griffith, noting the rarity of this condition in early life, reports two cases occurring in children aged ten years and six months respectively. He states that duodenal ulcer is undoubtedly a cause of melena neonatorum, the majority of cases of ulcer belonging to this period; and Moynihan has quoted from medical literature sixteen cases of melena in the first week of life in which duodenal ulcer was found at autopsy. Ulcer is also discovered occasionally in atrophic infants later in the first year.

The Hospital Ship "Solace."—M. F. Gates says that this is the only available hospital ship in the United States Navy and one of the very few in the world. In the hospital department the capacity for patients is stated as nine officers, each having a separate stateroom and 234 enlisted men for whom there are in place 166 fixed berths, the others being provided for in hammocks and cots. There are three wards on the hurricane deck, with twelve, ten, and eight berths, used as isolation wards for tuberculosis and for the diseases of childhood which are nearly always brought along by the drafts of young recruits of our enlisted force. The hospital facilities include a laboratory with microscope, ultramicroscope, incubator, laboratory animals, etc., a special dark room equipped for nose, throat, and ear work and for ophthalmoscopic examinations, a light ophthalmological room with 20-foot space for vision testing, dispensary, general operating room with two glass topped tables and with fully equipped sterilizing room adjoining, an exceptionally well equipped *x*-ray and electrotherapeutic room, well equipped dental office, three strong rooms for insane and alcoholic patients, two dressing rooms, electrically equipped diet kitchen, steam laundry, steam and formalin disinfecting chamber, and refrigerating morgue.

Acute Ailments in Narcotic Habitués.—G. E. Pettey notes the almost certain fatality of acute ailments, such as typhoid fever and pneumonia, when occurring in these individuals, and attributes this fact to the arrest of peristalsis produced by morphine. This arrest may be overcome by means of strychnine if this is given in sufficient dose and at the proper time.

Infection.—D. H. Bergey states that it is quite appropriate to regard infection as a contest between the invading organisms and the tissues and fluids of the host, and that one knows at least a little concerning the offensive and defensive measures which are brought into play in the contest. When the body is in normal condition and all its defensive measures are fully developed it is able to protect itself against invading microorganisms. It is only when overwhelming doses of the organisms are introduced or when the normal defenses of the body are defective that disease results. The occurrence of infection is practically always due to some defect in the normal defensive powers of the body.

Swelling of Liver and Spleen.—K. L. Elsmer reports a case of a female aged 32 years in whom a considerable enlargement of the liver and spleen was associated with a high continuous fever. The following possible causative conditions were ruled out: pernicious anemia, myeloid leucemia, lymphoid leucemia, splenic anemia or Banti's disease, Hodgkin's disease, internal abscess, tumor, syphilis, and malaria. There was no proof as to the presence or absence of kala azar. Numerous consultants agreed as to the clinical findings, but disagreed on the diagnosis and treatment. They were unanimous that the patient could not recover, at least not without a splenectomy; nevertheless the patient recovered. The treatment had been the administration of sodium arsanilate and the use of *x*-rays and high frequency currents.

Plastic Iritis.—A. M. MacWhinnie notes the increasing frequency of this condition with adhesions of the iris to the anterior capsule of the lens. In its treatment he recommends suction massage by means of a cupping apparatus that he has devised. The object is to create a vacuum, steadily drawing the eyeball well into the cup and the iris away from the anterior capsule of the lens sufficiently for rupture of the adhesions. The method is not applicable to adhesions of months' standing, but is applicable to cases in which the adhesions have not existed longer than a week. The ideal procedure is the extraction of an ounce of blood from the temple, instillations of 5 per cent. atropine solution, and application of the instrument for from two to five minutes.

Scarlet Fever Complicating Pregnancy.—S. Herzstein

concludes that a pregnant woman is not immune to scarlet fever. The septic process of scarlatina, though of a severe type, is not always a source of danger to the puerperal woman. The scarlet fever and the puerperium may each run its usual course.

The Nature of the Virus of Measles. J. Goldberger and J. F. Anderson.

The Physician and Health Departments.—W. A. Evans advocates a wide campaign for the promotion of the health of the community under the leadership of the medical profession and with the enlistment of the various welfare organizations.

Tuberculin.—F. M. Pottenger obtains the best results by the use of progresingly increasing doses. A condition of hypersensibility is more apt to occur when the small dose at infrequent intervals is employed. Small doses cause hypersensibility to further doses of the same proteid while larger doses cause immunity to it.

Tuberculin.—C. A. Shepard attributes considerable value to the intravenous administration of tuberculin in the treatment of tuberculosis.

Abdominal Incisions.—J. E. Moore states that the day of the short incision is past in all but exceptional cases. He asserts that it is infinitely better to make the opening large enough to admit the hand without force than to contuse the edges of the wound by a forcible introduction of the hand or with retractors. Faulty wound healing has very often been due to too great or too prolonged pressure from retractors or to forcing a tumor through too small an opening.

Infarction.—H. T. Karsner and J. H. Austin conclude from their experiments that, regardless of general circulatory conditions, all infarcts of the kidney and spleen of the dog are first hyperemic, then hemorrhagic and finally become pale from coagulation necrosis. The hyperemia of the early infarcts is, in a general way, proportional to the vascular pressure within the organ as a whole, and is not due to reflux of blood from the veins. Agglutination of the red blood corpuscles is the earliest demonstrable change in the blood of the infarct; removal of pigment from the infarcted area is probably due to plasmatic diffusion; definite fibrin formation appears relatively late in the course of the condition. Necrosis progresses more rapidly in infarcts in those organs in which the general circulation is altered in some way (either from damming back of blood by vein ligation or from cutting down arterial supply) than in organs in which the general circulation is normal. The pallor of the white infarcts is due to decolorization of the contained conglutinated and coagulated blood: decolorization begins in a general way in the middle of the infarct and extends peripherally. Organization progresses as well in organs in which the general circulation is diminished as in those in which the general circulation is normal. Regeneration is seen, in the kidney, only in the occurrence of mitotic figures in the epithelium near the margin of the infarct; it is diminished by any decrease in the general circulation. Regeneration of the cells of the splenic pulp or follicles is not demonstrable even at the end of one week.

Mediastinal Glands.—J. H. Honeij states that enlarged glands occur more frequently on the right side than on the left. Enlarged glands may cause the signs which are often considered as those of early apical tuberculosis. They occur in both tuberculous and nontuberculous patients and probably occur as frequently in adults as in children. Positive tuberculin reactions may, therefore, in clinically negative tuberculous cases be due to enlarged glands in the mediastinum, etc., when apical signs are not present.

Thiersch Graft Following Radical Mastoid Operation.—C. F. Welty reports a series of twelve cases in which the graft was applied at the time of operation. Besides eliminating a second operation, consuming almost as much time as the first, this procedure only lengthens the original operation about fifteen minutes.

Treatment of Furuncles.—P. G. Skillern states that the treatment of furuncle is divided into that of the boil itself and that of the low opsonic index of the blood. In the very beginning the puncture of the papule with a pointed stick dipped in pure carbolic acid will often abort the boil or, if this is rather deep, the injection by a hypodermic syringe of several drops of liquid phenol, though painful for a few moments, is often effective. The author does not believe in incising a boil in its first stage when hard. It shortens the process in no way and leaves an entirely unnecessary scar. He says, scratch off the little central vesicle. This causes no pain but exposes the ulcerating hair follicle and sebaceous gland. Apply a Bier cup and suck out as much as possible of the exhausted serum and blood, the place of which is taken by fresh leucocytes in the fresh blood which are going to cure the furuncle. Apply a dressing of plain sterile gauze wrung short of saturation from a solution of normal saline with sodium citrate, and this he uses also for the after-dressing.

Virus of Measles.—J. Goldberger and J. F. Anderson have found that this virus can pass through a Berkefeld filter, and that it can resist desiccation for twenty-five and one-half hours. All attempts to produce reaction by inoculation of monkeys after the virus had been heated to 55° C. or above for fifteen minutes were negative and the authors, therefore, conclude that this degree of heat destroys its infectivity. Frozen infected blood, however, was still infective after being kept in a solid frozen condition for twenty-four hours, though there is a possibility in one case that there was a slight reduction of its virulence.

A Case of Suppurating Inguinal Ovarian Hernia; Operation; Recovery. J. J. Waddelow.

Surgical Gastric Disorders.—E. Stanmore Bishop states that surgical procedures are to-day utilized in six distinct phases of gastric and duodenal disease:—(1) Perforation of gastric or duodenal ulcers; (2) acute or chronic gastric or duodenal ulcer during its course before perforation; (3) gastrectasia due to pyloric obstruction consequent upon cicatrization of ulcers at or near the pylorus; (4) hour-glass stomach (bilocular, trilocular, etc.) also due to cicatrization of ulcers in other parts of the stomach; (5) adhesions around old lesions dragging upon or compressing portions of the upper digestive tract; and (6) gastric carcinoma.

National Health Insurance.—By E. J. Schuster. (See page 692.)

Lymphatism Occurring in the East.—A. Whitmore reports a series of sixteen cases of lymphatism, and states

that although he does not think that these cases give very much information as to the connection between lymphatism and the liability to the occurrence of sudden death upon slight provocation, or as to the mechanism by which such death is brought about, yet they are useful in showing that such a condition is not confined to Western peoples, but is probably as widespread in the East as in European countries; that it is not a condition in any way dependent upon race or environment, but exists among all races and in all climes.

A Case of Eclampsia.—G. de B. Turtle reports a case of eclampsia which presents the following points of interest: (1) There was a rapid improvement in the patient's condition under treatment before labor came on. (2) There was fall in blood-pressure and an accompanying rise in the output of urine. (3) There were three attacks of dyspnea which the patient had during the puerperium. (4) The convulsions which the child had and from which it succumbed were of a peculiar nature. With regard to the third point, the author is of the opinion that the patient had a clot somewhere, possibly commencing in the left femoral vein, as evidenced by the swelling of that leg, and that small emboli were cast off and carried up to the right side of the heart and so into the lung. There were never any physical signs in the lungs and there was no hemoptysis. The alternative idea was that these attacks were due to cardiac dilatation, but it is noted that they commenced with dyspnea and cough and the pulse became rapid afterwards. With regard to point 4, the possibility of cerebral hemorrhage could not be excluded, but the way in which the fits came on with tonic spasm, finishing with clonus and stertorous breathing, pointed to their being of toxemic origin.

Salicylates and Thyroid Activity.—H. Ewan Waller believes that aspirin and possibly other salicylates and allied drugs will be found of inestimable value in Graves' disease. One might avoid the gastric disturbance and possibly get still better results by local use of one of the easily absorbed salicylic compounds directly applied to the skin over the thyroid gland. The final result naturally depends on whether thyroid control or exhaustion will cure Graves' disease or otherwise, which is another question and is not discussed. Further, in view of the beneficial results recently obtained by thyroidectomy in inoperable cancer, similar benefit might be obtained by the use of aspirin in such cases, many of which are also unsuitable for thyroidectomy. Aspirin has been used for the relief of pain in cancer.

Mediastinal Causes of Chronic Cough.—H. French states that not a few cases of chronic cough in children are attributed in an indefinite way to adenoids or to tonsils and adenoids, or to mouth-breathing; but there is another cause at work in at any rate one group of these cases—namely, chronic enlargement, sometimes no doubt associated with tuberculous caseation, of the glands at the bifurcation of the trachea. When a large number of post-mortem examinations are made the fact obtrudes itself that the bronchial gland immediately below the right bronchus is affected far more frequently than is the gland upon the left side, and the right phrenic nerve is frequently seen to be displaced by the enlarged lymphatic gland in such a way as probably to be much irritated by it and thus to lead to attacks of purposeless coughing—that is to say, coughing which does not succeed in the bringing up of any sputum. In a certain number of cases it is possible to demonstrate the enlargement of this right bronchial gland by means of the *x*-rays.

"Comforter" Otitis Media.—W. H. Bowen believes that a large proportion of cases of suppuration of the middle ear in infants are directly due to the comforter, which acts by introducing oral sepsis.

Treatment of Torticollis.—F. B. Roth advocates the following method of employing tenotomy for this condition without the subsequent use of retentive apparatus. After division of the muscle and fasciæ by the open operation the head is firmly manipulated into an over-corrected position. The child is then put back to bed with the head between sandbags, and on the second or third day is allowed up and gentle passive movements are begun. On the fifth or sixth day active movements take their place, and after removal of the stitches the mother is shown how to superintend the carrying out of these movements at home for five minutes twice a day.

Suppurating Inguinal Ovarian Hernia.—J. J. Waddelow reports a case of this condition, and notes that hernia of the ovary is usually an infantile condition and associated with a patent canal of Nuck as a congenital hernia. Hernia of the ovary coming on in adult life by itself and not as a portion of a preexisting hernia is a rare occurrence, as is also the absence of any sac. These conditions were present in the case reported.

The Mode of Transmission of Leprosy. T. Lindsay Sandes.
A Note on the Transmission of Leprosy. E. C. Long.
The Ophthalmo-Reaction of Calmette in the Early Diagnosis of Phthisis. A. Stroud Hosford.
Nasal Obstruction and Its Consequences in School Children. C. E. Reynolds.

Transmission of Leprosy.—T. Lindsay Sandes states that, considering the enormous numbers of lepra bacilli in the infiltrated or ulcerated skin and nasal mucosa of an active "tubercular" leper and the ingestion of bacilli by certain insects, direct contact and transmission by flies, fleas, mosquitos, or other insects are possible modes of spread of the disease; but such infection, if it ever does take place, is accidental and exceptional. Having found acid-fast bacilli answering, as far as the imperfect tests permit, to the characteristics of lepra bacilli in a considerable proportion (about 30 per cent.) of specimens of *Acanthia lectularia* up to sixteen days after feeding on lepers, there is reason to believe that this species of insect constitutes a very important agent in the spreading of leprosy. Unfortunately this view can be proven with finality only by the application of bugs previously fed on lepers to the persons of healthy individuals with the resultant development of the disease, unless, indeed, it be found, as there is some reason to hope, that certain monkeys and anthropoid apes are susceptible to inoculation with leprosy.

Transmission of Leprosy.—E. C. Long thought of the possibility of the bacillus of leprosy being carried by vermin. With a view to testing this hypothesis, bed-bugs obtained from huts which had never been inhabited by lepers were caused to bite lepers in the neighborhood of leprous nodules on the face. The bugs were then killed and the alimentary tract and its contents examined. In every bug that bit freely a bacillus was found which in shape, size, and staining reactions was similar to the *Bacillus leprœ*.

Ophthalmo-Reaction in Tuberculosis.—A. S. Hosford concludes that a negative result by no means excludes pulmonary tuberculosis; some very advanced cases fail to give a reaction. He has never obtained a positive result except in true cases. He has never seen any bad results whatever from the use of the test as regards the eye. If in a suspicious case the patient fails to give a reaction, then the test should be applied on three different occasions with an interval between each application of three to four weeks.

Nasal Obstruction.—C. E. Reynolds discusses the subject of mouth-breathing in school children, noting the causes in order of frequency as follows: adenoids, enlarged turbinate bones, thickened and deviated septum and spurs, and nasal polypi.

Berliner klinische Wochenschrift.

August 28 and September 4, 1911.

Treatment of Aphonia Spastica.—Seifert emphasizes the extreme difficulty of this problem, but he is not so pessimistic as some of his colleagues. There is much opportunity to choose cases having advantage in prognosis, and also cases suited to particular plans of treatment. He would first isolate a hysterogenous group, such as occur in males as well as females. The prognosis of these cases is often relatively good in the latter, and the treatment may be summed up as the psychophysical. A second group is made up of the so-called reflex cases. A third group comprises the occupation neuroses in the widest sense of the term. There may also be cases which are not comprised in any of these groups and it is claimed that on this account they are much the more serious. A fifth group is characterized by its central or cerebral origin. The treatment of the various types does not lend itself to summing up.

Oculoorbital Symptoms from Disease of the Nasal Sinuses.—Onodi concludes his study by advising therapeutic intervention where the rhinoscopic finds are negative as far as the sinuses are concerned and the turbinals are so swollen as to prevent the view higher up. It not rarely happens that resection of the middle turbinal and opening the ethmoidal and sphenoidal cells remove the ocular symptoms. In obscure cases of visual trouble the ophthalmologist is justified in taking this radical step.

Modern Laryngorhinology as a Separate Branch of Medicine.—Killian wishes to consolidate rhinology, laryngology, and bronchoscopy firmly, using special clinics and other utilities toward this end. He deprecates any attempts to subdivide them further. The joint field is naturally very wide and involves all the sinus work. Endoscopy is required in all the special fields involved, and radiography has also a general field of applicability. The combined specialty is preeminently one for diagnosis and exploring procedures. Killian evidently wishes to leave the ear to itself, as on account of intracranial complications this has also become a very wide discipline.

Results of Operations for Myopia.—Von Feilchenfeld states that renown achieved by Fukala's operation of extirpation of the lens for high grade myopia was short-lived. Many reports followed of detachment of the retina as a result of intervention. The author's personal expereience is as follows: In twelve years he has extirpated eleven lenses in eight patients. The indications were as follows: Objective—myopia above 16°. The vitreous must be clear to transillumination. The vision on both sides should be readily correctible. Subjective—incapacity to earn living, etc. As far as the latter goes the author believes that spectacles may be made to relieve the condition, and gives instances of rapidly advancing myopia successfully controlled. But cases occur in which high numbers cannot possibly be worn with comfort and which are made worse by such glasses. In the author's eleven operative cases there was no succeeding detachment of the retina. Hirschberg had but one detachment in twenty-four cases. Thus far the author has noted no other untoward sequence of any sort. The technique requisite for successful intervention which supplements the proper selection of cases is minutely given.

Banti's Disease.—In his series of articles on cirrhosis of the liver Klopstock comes finally to Banti's disease. Our present knowledge of the latter may be summed up as follows: In some of the cases the course is prolonged for years. The symptoms at first comprise anemia and enlarged spleen, and there is difficulty in distinguishing the cases from those of splenic anemia. At a later period, after hepatic cirrhosis has developed, the diagnosis between Banti's disease and ordinary cirrhotic liver becomes difficult. A special anatomical basis for the former cannot be predicated, despite claims to the contrary. Again etiologically we find no alleged causes of Banti's disease which have not already been claimed for ordinary cirrhosis (lues, malaria, etc.). The sole test at present of Banti's disease seems to proceed from the treatment. Many cases have improved notably after splenectomy, something which would be inconceivable for ordinary hepatic cirrhosis, in which splenomegaly has been looked on as a simple consequence of the former. The striking success attending splenectomy for Banti's disease shows plainly that the latter originates in the spleen, which produces certain toxins that are able to give rise to the blood and liver lesions. It is better to regard Banti's disease as a splenic syndrome rather than an affection *sui generis*.

Veronal in Seasickness.—Citron asserts that veronal has thus far proved itself the best medicament ever employed for seasickness. It is, however, sometimes impossible to administer it, as must necessarily be the case with drugs in general, owing to the constant rejection of all ingesta by the stomach. He therefore recommends the use of solutions of sodium-veronal by the rectum, and also suggests the use of the same drug in suppositories. Improvement from this use of veronal is usually in evidence inside of an hour. After this interval the patient is even able to take nourishment. The same treatment should be useful in carsickness.

Demonstration of Lipoids in the Blood.—Döblin and Grote state that we are as little able to understand something of the constitution of lipoids as to devise quantitative methods in connection with lecithin, cuorin, etc. It is claimed, however, that the percentage of lipoid material in the blood—or rather determination of an increase or diminution—may be recognized to such an extent as to be of some clinical service. The chief employment of the reaction is at present in regard to pregnancy and the climacteric. The method of use consists naturally in making lipoid-soluble extracts of blood, using different extractive substances. It is said that lipoids are decreased during menstruation and increased after conception, castration, and the menopause.

New Pathological Coloring Matters in the Urine.—Lehmann and Zinn state that twenty hours after laparotomy for adnexal tumor the woman passed a urine of a deep cherry color, previously unnoted. Ether anesthesia had been used. The patient showed great prostration, icterus, and after two weeks a syndrome of spinal paralysis. Hemoglobinemia and methemoglobinemia were present for days. The patient succumbed to sepsis from decubitus. The authors believe that the ether caused a toxic dissolution of the blood, while the hemoglobinemia was responsible for transverse spinal degeneration.

Münchener medizinische Wochenschrift

August 29 and September 5, 1911.

Indications for Use of the Peristaltic Hormone.—Fodkel believes that this substance is of remarkable efficacy if the cases are properly selected. He cites a case in a child of pain in the left hypochondrium with obstinate constipation. Purgatives brought away impacted feces without any permanent benefit. The health failed and a paresis of the lower extremities developed, with tendency to ascend. A most thorough examination failed to reveal sufficient data for a diagnosis. The nature of the fecal retention, whether atomic or spastic, could not even be decided. Upon the theory that the case was one of paralytic ileus a dose of 11 ccm. of the hormone was injected into the buttock. A painful local reaction followed but without constitutional disturbance. For the first three days no benefit was noticeable. Ordinary purgatives had to be used as before. Upon the fifth day a spontaneous evacuation occurred with normal feces, and daily stools of the same type succeeded. The case was followed only three weeks, but pain continued in the left hypochondrium.

Hyperglobulia.—Von Bergmann and Plesch, in discussing compensating hyperglobulia quote Münzer's view of compensation. If with normal blood the peripheral vessels, by contracting, shut off the normal balance of oxygen in the tissues, the dangers of tissue asphyxiation must be met by hyperglobulia. This view cannot be proved but is physiologically sound. Nevertheless we do not as a rule see hyperglobulia in arteriosclerosis, and it may be absent in the severest cases. Naturally hyperglobulia is not necessarily compensatory, for it could be due to hyperfunctioning of the bone marrow. Again if compensatory it need not depend on a single type of compensation.

New Methods of Treating Epilepsy.—Fackenheim calls attention to a new resource introduced of late years in the treatment of epilepsy. In 1908 Dr. Self of Texas claimed to have seen cured permanently a chronic epileptic following a rattlesnake bite. The snake venom or crotalin had already been used for this purpose and Spangler reported some results very recently. The present author obtained some of the venom for testing and found it to exert a specific or quasi specific action on the disease of the greatest promise. It is of course, true that the number of years which have elapsed since the treatment was first used is far too short to be conclusive.

Modified Coffee.—Prof. Harnack has written at length on this subject. The specifically pernicious action of coffee is exerted on the stomach and only indirectly on the heart. The active substances are volatile and brought out by roasting. Coffee is essentially different from tea, being more hypertensive. Tea is even hypotensive. The rational attempt is toward relieving the coffee of these substances, while the caffein remains. A recent process deprives the coffee of the pernicious volatile substances in such a manner that it still remains coffee.

Etiology of Hypertrophy of the Prostate.—Wilms refers to three prevalent theories of origin of prostatic hypertrophy, viz., the gonorrheal, arteriosclerotic, and neoplastic, and states that none has proved adequate to account for the disease. We know that there is an intimate connection between the prostate and testicles, and that is about the extent of our knowledge of the causation of prostatic hypertrophy. The surprising amelioration which follows castration and ligation of the vas deferens has led the authors to test the results of radiography of the testicles, this being also suggested as the result of the rays on uterine myoma. Recent studies have shown more strongly than ever the analogy which exists between the nodules of enlarged prostate and uterine myomata. It is possible that an overproduction of internal secretion of the testes is able to cause the prostatic enlargement, and a similar theory is held for the ovarian origin of uterine myomata. But one case has thus far been tested with the rays. This was in a man aged 69, with complete retention of the urine. Prostatectomy refused. Both testicles were radiated and the improvement was constant and pronounced. It began four days after the first radiation. Only two sessions seem to have been required to produce absolute recovery.

Ascending Colon Obstipation and Appendicitis.—Stierlin states that in a large number of cases of severe constipation with symptoms of chronic appendicitis the cause is fecal impaction in the ascending colon and cecum. In skiagraphy with bismuth, it is noted that the shadow of the latter persists for a long time. The ascending colon is much distended and sacculated in the region corresponding to the impaction. The causation of this obstipation may be both functional and mechanical. The former comprises both atony and so-called antiperistalsis. The latter consists of cicatricial malformations and other deformities. This stagnation in the ascending colon readily sets up obstipation.

Pseudofever in Children.—Avellis has often noted in children up to 8 years of age a temperature rise of over 1° C. in which the patients were subjectively normal, ate well, and showed no trace of emaciation after prolonged intervals. Such children go from one practitioner to another and get no relief. They are kept in bed, and while no real diagnosis is made a slight tonsillar infection or some other local ailment is assumed to exist. Thermometry simultaneously in several localities in the body shows such discrepancies that a general febrile reaction seems absent. If subjectively and otherwise well the child should not be kept in bed. The real causes of the slight, perhaps local, temperature rises must be varied. The "fever" often yields to the use of artificial sour milk, which seems to connect these particular cases with intestinal fermentation.

Deutsche medizinische Wochenschrift.

August 31, 1911.

Action of Radiant Energy on Experimental Tuberculosis.—Flemming and Krusius continue their researches on the action of radium, mesothorium, solar light, etc., upon experimental tuberculosis of the eye. They regard it as absolutely certain that the rays exert a definite action both on the germs and tissues, and that the disease intensity is weakened thereby. The solar rays surpass the emanations in bactericidal power. The so-called high solar rays are two or three times as powerful as the deep solar rays. Rays and emanations doubtless act favorably on the tissues chiefly by activating the blood-vessels.

Indications for Opening and Evacuating the Ethmoid Cells.—Stenger refers to endonasal procedures only. Ethmoidal disease is set up by ordinary colds, acute infectious diseases, adenoids, unskilful surgery, neoplasms, and foreign bodies. It may also be derived from disease of one of the other sinuses, and disease of one sinus readily mimics that of another. The symptoms comprise alterations in volume, abnormalities of secretion, and frequent participation of other sinuses, the orbits, the throat, larynx, etc. Pulmonary complications are frequent, chiefly asthma, and of course all the ill effects of mouth breathing will be apparent. The treatment may be conservative or operative. The former requires much time and is limited in scope. The mucosa must have its swelling reduced and drainage must be secured. We know so little about the true nature of many of these cases that conservative measures may be a waste of time. However, they suffice in simple and mild forms. Operations do not have to be radically performed. It may be possible to rank these procedures as conservative. When we have evidence or belief that there is an acute empyema of the ethmoid no time is to be lost before resorting to a radical operation.

Difficult Detubation after Diphtheria.—Martens has a series of 390 tracheotomies for croup with a mortality of 31.6 per cent. Of the 247 cases which recovered the tubes all came away save in two patients, who left the hospital before their regular discharge. Removal of the tubes in tracheotomia inferior must be promptly performed, but in tracheotomia superior the patient may go home with the tube *in situ*. The diphtheria service at the Bethany Hospital, Berlin, is enormous and it seems that primary intubation is never done there although tubes are inserted to prevent secondary stenosis.

Herpes of the Left Nasopalatine Nerve.—Bauer mentions some clinical forms of herpes of mucous surfaces and then relates a case of the preceding which comes in part under the head of zoster since it affects a twig of the trifacial. It belongs to so-called partial zoster. It is not, of course, a simple matter to distinguish a simple herpes from a partial zoster. The case was called by the author herpes neuralgicus, to further distinguish it from true zoster.

Insurance Medicine.

Four Prominent Causes of Mortality.—Luther Sexton says that of the many elements interfering with longevity of the human race, intemperance in drinking is one of the most important. The drunkard is not only exposed to various diseases, but is very apt to get into business or social difficulties that make his life hazardous. Drunkards, too, are most apt to carry on excesses in sexual relations and are exposed to infection of venereal nature. The descendants of a drunkard, Frau Jukes, who lived between 1740 and 1800, have been traced. Of the 709 found, 106 were illegitimate, 142 were beggars, 64 were charges of the State, 181 females were prostitutes, 69 were convicted of crime. These are supposed to have cost $1,250,000 during the period of seventy-five years

Heredity is another important element in longevity, though only a few diseases are inherited. The tendency to disease is, however, often handed down from parents to children. The following ten laws of heredity are acknowledged to be correct (Church and Peterson): (1) The child tends to inherit every attribute of parents. (2) Contradictory attributes cannot be inherited from both parents. (3) The child may inherit the attributes of either parent solely. (4) It may inherit the qualities of one parent in some respects, and of the other in other respects. (5) It may inherit the father's attributes for one period of existence, and of the mother's for another. (6) Some attributes have the quality of prepotency, or the tendency to push aside or overrule other attributes. (7) Attributes which are similar in both parents tend to become prepotent giving rise to convergent or cumulative heredity. (8) Attributes may be transmitted in latent form from one generation to another, to another in a third or fourth, or still more remote generation—a phenomenon termed reversion. (9) Attributes tend to appear in the progeny about the same time of life in which they became manifest in the parents. (10) Attributes of the father tend to be inherited by the sons, and of the mother by the daughters. Heredity plays an important part not only in tuberculous and cancerous affections, but likewise in albuminuria, rheumatism, gout and many other diseases. We do not inherit tuberculosis, but we do inherit a lessened vitality, or a tendency to contract tuberculous infection. Underweights are usually people who have inherited such a lessened vitality and they run the further risk of infection from their underweight brothers or sisters who are apt to be infected.

Syphilis and disease resulting from it add largely to mortality. The success of salvarsan, which is beginning to be doubted by some observers, may cause a rearrangement of our mortality statistics for syphilitics. Some specialists claim that one in six in the city population suffers from syphilitic taint. Some say that the negro race is quite syphilized, and tuberculosis with syphilis will finally end the race question. Sexton thinks that one in twenty-five is a more reasonable ratio of syphilitic infection. Syphilitics have double the mortality otherwise expected in a similar class of people. The following rules are followed by most conservative medical directors: No person under active treatment for a well defined case of syphilis is insurable until six years after the date of infection, and two years of actual anti-syphilitic treatment has been carefully carried out. Any evidence of tertiary syphilis is a ground for rejection.

Malaria has had much of its venom or sting extracted from it. The fearful mortality among the laborers in Panama under De Lesseps should be compared with the results of the work done by Col. Gorgas. Similar work on a smaller scale is being done in the South. Still malaria is fearfully prevalent, though care in treatment and a campaign of education should diminish it very much. In Italy it has been reduced sixty-five per cent by the free use of quinine. All duty on quinine should be removed. Boards of health should distribute it free to the needy population.

Overeating is a foe of longevity; it may result in gout, Bright's disease, and vascular disease. Gout is a frequent contributary cause in deaths from apoplexy, heart disease, or kidney trouble. The average well-to-do person eats twice as much as he needs.—*Proceedings of the Medical Section, American Life Convention, New Orleans,* February, 1911.

Determination of Cause of Accidents from Results of Autopsy.—Leopold Feilchenfeld says that in many instances the occurrence of accidental injury can only be diagnosed at autopsy. He has gathered material from one hundred and twenty such actual cases to illustrate the difficulties and the proper procedures. Cardiac death, death from kidney disease and from injuries of the intestines are first to be considered. Cardiac death does not occur in the presence of a normal heart. The adaptation of young men's hearts to the strain of athletics is a proof of this. But complete ability to follow the usual occupation is not proof that the heart was sound just before an accident; only functional tests can determine this question. A diseased heart often gives way in the face of very small stress. Autopsy may show sclerosis of the coronaries and of the aorta and degeneration of the heart muscle. Frequently microscopical examination alone shows morbid changes.

Apoplexy and traumatic cerebral hemorrhage are differentiated by the seat of the lesion. Now accidental hemorrhage usually occurs in the Sylvian fossa or in the ventricles. Collection of blood between the brain coverings, in the cranial fossae, or in the substance of the brain itself are usually due to injury. Occasionally typical cerebral hemorrhage—apoplexy—may be caused by an accident, accompanied by an unusual rise in blood pressure. Psychic causes may determine the latter.

Among abdominal conditions, appendicitis is frequently made acute by some injury. Adhesions and shortening of mesentery show that the affection is of old standing; the presence of fresh blood in peritoneum or free in the abdominal cavity give proof of the occurrence of an injury. Accidental incarceration of intestinal loops is usually not traceable to injuries; congenital defects play a more important role in these cases. Other injuries of intestines or internal viscera may, however, be caused by external accidental causes without showing external evidence of such accidents.—*Zeitschrift für Versicherungsmedizin,* June, 1911.

Locomotor Ataxia Following but Not a Consequence of an Accident.—Rigler details the history of a patient who fell from a considerable height, and suffered a fracture of the right leg and of several ribs. Convalescence was prolonged and accompanied by nervous symptoms: headache, slight inequality of pupils, etc., appeared at the time. The earning capacity was adjudged to be diminished by 50 per cent, and corresponding indemnity was allowed. Four years later the patient developed symptoms of tabes dorsalis and claimed that the accident was the cause of the disease. Expert decision was against the claim because of the following considerations: Although the rôle of injury in the etiology of locomotor ataxia has not been definitely settled, yet no authentic cases with injury as the only possible factor have been published. At any rate, in the present instance, the injury was not of a nature to affect the spinal cord. Changes in the pupils were noted before symptoms that could be referred to the accident. The injury could not be considered even to have caused rapid progress in a preexistent disease, as the symptoms appeared a considerable period of time after the accident. These considerations justified refusal

of the claim for increased indemnity.—*Zeitschrift für Versicherungsmedizin,* June, 1911.

Arterial Degeneration in Women.—T. M. Bruce presents a number of important facts relating to the relative incidence of arterial degeneration in women. According to the Registrar-General of Great Britain, in his Seventy-first Annual Report (for 1908), on the average of the last eight years the details at all ages from cerebral hemorrhage (together with apoplexy and hemiplegia) correspond to a death rate of 666 per million for males and of 750 per million for females. At ages above 35 it accounts for the deaths of 2,083 in a million men and of 2,284 in a million women. In the 20 years intervening between the thirty-third and fifty-fifth years women fall victims to the disease in greater proportion than men, while at ages above 55 years the mortality is higher among men. The temptation is strong to refer this remarkable liability in women to disease of the cerebral arteries to nervous influences, although many other explanations might reasonably be offered. One is also disposed to connect it with the familiar disturbances of the circulation in neurotic and hysterical women, attacks of precordial oppression, globus, flushing, faintness, and false angina, ending often in tears and other emotional manifestations.—*Lancet,* July 22, 1911.

Prospect of Life in Cases of Cardiovascular Degeneration.—T. M. Bruce states the conclusions which he has reached in a study undertaken to determine the prospect of arrest of activity and recovery of health or of disablement in various degrees or of remote or early death in the different kinds of cardiovascular degeneration. He found, for example, that in the course of thirteen years one-half of his cases of syphilis of the heart and aorta had died, and died at the early average age of fifty-two, while a decidedly smaller proportion of his cases of physical strain had perished, and these at the age of sixty-six. Again, he found that syphilis of the aortic region runs its fatal course in 5¼ years; degeneration connected with glycosuria in 12½ years, the patient dying on an average ten years later than the victim of syphilis.—*Lancet,* July 22, 1911.

Insurance for Medical Men.—*The Lancet* of July 15, 1911, reviews the work of the Medical Insurance Committee, which is composed of members of the British Medical Association, and which has now been carrying on its business close upon four years. The committee was started to secure for medical men the best terms possible for all classes of insurance, and after paying working expenses to distribute any surplus to deserving medical charities. It has fulfilled its objects in a satisfactory manner. To quote from the chairman's report, which was adopted at a recent meeting: "That the main object has been achieved is demonstrated when it is borne in mind that up to the present the committee has returned to medical men insuring through the agency, in the form of rebates, a sum exceeding $7,500, and has handed over to medical charities some $700." The "Red Cross" Doctor's Policies have been much utilized, as is proved by the large increase of business. It is stated that physicians can obtain substantial permanent benefit for themselves under the operations of this organization.

Malingering and the Workmen's Compensation Act.—J. H. Keay states that much is now being said about malingering. There is no medical man practising in an industrial district who is not well aware of the fact that the most fruitful source of malingering in England is the Compensation Act. The worker has only to make a complaint, and if the amount asked for is not more than a few pounds the company with which the employer is insured will not go to the expense of disputing it. What is the remedy? So far as the author's personal experience goes, industrial accidents and poisoning are far more frequently due to the carelessness of the worker than to defects in machinery; and yet England is the only country in Europe where the employer has to bear the full cost. Were the worker compelled, by a deduction from wages or otherwise, to pay a share, this would be a stronger check against malingering than any that has yet been proposed. And while much is being said as to free choice of doctor and payment according to attendance leading to malingering, there is now before the House of Commons an Insurance Bill, which professes to be national, in which the most prevalent cause of malingering is left untouched.—*British Medical Journal,* July 15, 1911.

National Health Insurance.—E. J. Schuster, in commenting upon the National Insurance Bill now before the House of Commons, states that as regards both the measures affecting the general health and those affecting the insured persons individually the provisions of the bill are insufficient to secure the fulfilment of the far-reaching hopes which have been held out by its author and its more enthusiastic supporters, and above all that the voluntary agencies which have hitherto been active in the fight against disease will be as necessary as they were before. It would be a disastrous result of the legislation for compulsory insurance if the efforts of these voluntary agencies were to be relaxed, or if they did not continue to receive the unstinted support of the public.—*Lancet,* September 9, 1911.

Appointment of Medical Examiners.—Ambrose Talbot says that the appointment of examiners depends frequently on the agency force, agents being furnished with blank applications for appointment as examiners, which applications they often "peddle" among physicians. The latter are requested to insure in the company or buy its stock. This method of selecting examiners should be changed, application blanks being sent out directly by the medical department. Appointment should not be a part of a bargain for a policy in the insurance company. If possible, a medical examiner should be appointed in a town before the agent has been sent to visit this town. The data given by the American Medical Directory should assist the medical directors in making choice among candidates. Best examiners for large towns are young men with hospital training who have not been in practice long enough to have their time fully occupied and whose hospital training offsets the short time they have been in practice. It would be well to have papers showing the relations between the medical profession and insurance companies read before county medical societies. Both are interested in questions of public health, and the companies are interested in all measures which will elevate the standard of the profession and secure them efficient examiners.—*Proceedings of the Medical Section, American Life Convention, New Orleans,* February, 1911.

Industrial Antituberculosis Work.—An important phase of the welfare work among employees which is now generally recognized as an essential condition of industrial progress is the introduction into a large manufacturing establishment of a scientific system of studying employees for evidences of incipient tuberculosis. It is reported that the International Harvester Company, actuated by motives both of philanthropy and of self-interest, is about to inaugurate this investigation among its 30,000 employees. Expense will not be allowed to interfere with the plan to aid the employee. The object will be to find out what number of employees of the company are suffering from tuberculosis and what remedies to adopt for their cure. For the latter purpose it is proposed in the complete plans to have an expert at each of the company's plants to give advice and assistance to those afflicted. Ultimately it is intended to install the scientific scheme in all of the workshops if it is found feasible. The expert will watch every employee at his plant, his method of work and his failings, will endeavor to detect the occurrence of abnormal fatigue, and by other means to discover incipient cases of tuberculosis.

Book Reviews.

Nervous and Mental Disease. Monograph Series No. 8. Mental Mechanisms. By William A. White, M.D., Author of "Outlines of Psychiatry;" Superintendent Government Hospital for the Insane, Washington, D.C.; First Lieutenant, Medical Reserve Corps, United States Army; Professor of Nervous and Mental Diseases, Georgetown University, Washington, D.C.; Professor of Nervous and Mental Diseases, George Washington University, Washington, D.C., and Lecturer on Insanity, U. S. Army and U. S. Navy Medical Schools. Price $2. New York: The Journal of Nervous and Mental Disease Publishing Company, 1911.

The author of this monograph has confined himself to an explanation of those fundamental principles of psychopathology which appear to him to be essential to an understanding of the problems of present-day psychiatry. Naturally the book is of greatest interest to the student of mental diseases. The general medical reader, however, who wishes to keep up to date, and has not the time to read lengthy treatises, in various languages, will find certain parts of the book both instructive and fascinating. The subject matter of the various chapters briefly stated may serve to outline the scope of the work: The constitution of consciousness and the relation of mental and physical; types of reaction, defense and compensation. The content of consciousness, dreams, symbolism, the psychosis, folk-lore; the complex; ; hysteria, current conceptions and clinical theories; the psychological approach to the problem of art; psychoanalysis; preventive principles in the field of mental medicine. To the general medical reader the chapter on the content of consciousness as illustrated by dreams, the content of the psychoses and certain phenomena of the content of race consciousness (folk-lore), will be of especial interest; also the chapter on hysteria, and that applying the principles of psychopathology to an explanation of the problem of art, both, as the author states, from the standpoint of the creation of art and the nature of its appeal. The chapter on preventive principles calls attention especially to those mental disorders that are dependent upon purely psychological factors. Among the physical causes of insanity, syphilis and alcohol are spoken of as being responsible for about one-fourth of the insane. The effects of child labor and of the employment of women are discussed.

The Surgery of the Diseases of the Appendix Vermiformis and Their Complications. By William Henry Battle, F.R.C.S., Surgeon and Joint Lecturer on Surgery to St. Thomas' Hospital; Formerly Surgeon to the Royal Free Hospital; Formerly Assistant Surgeon to the East London Hospital for Children; Hunterian Professor of Surgery at the Royal College of Surgeons of England, etc.; and Edred M. Corner, M.A., M.B., M.C., F.R.C.S., Surgeon in Charge of Out-Patients and the Surgical Isolation Wards to St. Thomas' Hospital; Lecturer on Practical Surgery; Surgeon to the Hospital for Sick Children, Great Ormond Street; Formerly Erasmus Wilson Lecturer at the Royal College of Surgeons, etc. Second and Enlarged Edition. Price $3.00. New York: William Wood & Co., 1911.

Although issued as recently as 1904, the first edition of this book has been subjected to very extensive alterations and additions necessitated by the contemporary advances in the subject treated, and the second edition appears, therefore, in a somewhat enlarged form. The plan is again followed of presenting as many as possible of the known facts about appendicitis in a compact and easily available form. On reading the book it is quite evident that the authors have succeeded admirably in accomplishing what they have set out to do, due credit being given to the important rôle played by American surgeons in the development of our knowledge of the disease. The preliminary chapters deal with the anatomy, physiology, and pathology of the appendix, in the course of which some stress is laid on the possibility of the production of stricture of the organ from irritation due to the assumed presence of iron particles in wheat flour ingested as food. The treatment of appendicitis is presented in a very complete manner. The numerous methods of approaching the appendix are fully described, and particular attention is naturally extended to the procedure already well known by the name of one of the authors (Battle). From the writers' collected statistics they have apparently shown that the disease is least frequent and most fatal after middle age, and most frequent and least fatal between twenty and thirty years of age. From the study of a series of one hundred personal operative cases it is shown that the highest percentage of mortality, even in operations done within forty-eight hours after the onset of the illness, falls on patients during their first attack of the disease. It is, therefore, urged that operations at the beginning of the attack should be advised in such cases instead of postponing the operative treatment until the quiet interval after the attack. Notwithstanding the apparently successful results obtained in this country and elsewhere with the conservative methods of treatment, it is quite probable that this view will soon obtain even more generally than at present. In this connection it is also shown that the mortality from operation is *nil* as long as the infection remains within the appendix, and increases rapidly as the process extends outward from the organ. It appears from the observations presented in a subsequent chapter that the presence of an appendical abscess does not necessarily destroy the appendix, and that a certain number of patients may have recurrent and even fatal attacks of appendicitis after the abscess has been drained. A very interesting chapter is that on the complications of appendicitis and also on the peculiarities of the disease in different periods of life. The book here referred to must be acknowledged as satisfying a demand for a complete yet concentrated presentation of this most important subject, and the authors are to be complimented on the success of their undertaking.

Tuberculosis Hospital and Sanatorium Construction. By Thomas Spees Carrington, M.D. 150 pages. Price 25c, postage prepaid. Free to all members of the National Association for the Study and Prevention of Tuberculosis upon Application to the Executive Office, 105 East Twenty-second Street, New York.

All municipalities, State and county authorities, as well as individuals interested in the construction of sanatoria or special hospitals for the care and housing of tuberculous patients, must feel indebted to the National Association for the Study and Prevention of Tuberculosis, its secretary, Dr. Livingston Farrand, and its assistant secretary, Dr. Thomas Spees Carrington, for bringing out so valuable a work as this. The book contains virtually all that is known of sanatorium construction, and a mere enumeration of the headings of the six sections will show the large scope of the book.

Chapter I deals with site and grouping of buildings, with sub-chapters on transportation, meterological conditions, extent and nature of the land, lighting, water, and sewerage. Chapter II describes the best methods to construct an administration building and various auxiliaries, such as ice houses, stables, milk houses, etc. Chapter III gives suggestions for planning buildings in which administration and patients' quarters are combined. Chapter IV gives admirable descriptions of hospitals for advanced cases. Chapter V describes the lean-to type, and Chapter VI the cottage type of building. The entire volume is richly illustrated with no less than 120 pictures of projected or existing institutions.

Handbuch der speziellen Chirurgie des Ohres und der oberen Luftwege. Herausgegeben von Dr. L. Katz, Spezialarzt für Ohren-, Nasen-, und Halskrankheiten in Kaiserslautern; Dr. H. Preysing, Prof. der Ohrenheilkunde, Ord. Mitglied der Akad. für Prakt. Medizin zu Cöln a. Rh.; und Dr. F. Blumenfeld, Spezialarzt für Nasen,- Hals,- und Lungenkrankheiten in Wiesbaden. 1. Bd., Lieferung 1-2, Preis Mk. 8. 1. Bd. Lieferung 3, Preis Mk. 6. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1911.

This work is to consist of four volumes, which are to be issued in parts. Three parts of the first volume have already appeared. The object of this work is to furnish the specialist in otology and rhinolaryngology with a presentation of the modern aspect of these subjects from the practical viewpoint. The rapid progress made in this field during the past decade has justified the preparation of a book dealing particularly with the operative surgery of the ear, nose, and throat; first by means of a detailed description of the topographical anatomy of these regions, and then by a clear exposition of the various operative methods. The first two numbers take up the topographical anatomy of the skull, with the exception of the nasal cavities and the ear. This portion of the work is written by J. Sobotta, Professor of Anatomy in Würzburg, and contains thirty-seven full-page plates in colors. In beauty and clearness these surpass anything that has yet been attempted in anatomical art. The third part describes the topographical anatomy of the nasal cavities and of the accessory sinuses. The author is A. Onodi, Director of the Rhinolaryngological University Clinic in Budapest. In addition to numerous illustrations in the text, there are thirty full-page plates. The complicated anatomy of this region presents a difficult task to the artist, nevertheless the illustrations are as natural as the well-prepared anatomical specimens or dissections.

Society Reports.

AMERICAN CLIMATOLOGICAL SOCIETY.

Twenty-eighth Annual Meeting Held at Montreal, Canada, June 13 and 14, 1911.

The President, Dr. John Winters Brannan of New York, in the Chair.

Tuesday, June 13—First Day.

President's Address.—Dr. John Winters Brannan of New York said that for the first time in the history of the society they had come together outside the boundaries of the United States. At the meeting last year in Washington Dr. Hinsdale's interesting paper on the recent floods in France gave rise to an animated discussion on the influence of forests in regulating the flow of rivers; the opinions expressed were so divergent that it was suggested that the present meeting should have a symposium on the relation of forest growth to the increase or diminution of floods. The speaker said he would discuss only the relation of forest growth to neighboring water courses and the effects of deforestation upon the regularity of their flow. Until quite recently there seemed to be a general agreement that forests controlled the flow of streams, and that the extensive cutting away of the forests had increased the frequency and height of floods and had intensified the periods of drought. But now they were informed that there had been an increase of floods and that there was no statistical evidence to prove that the forests had any material effect upon either the high or the low water of rivers. During the past few months the speaker had made some study of the documents and arguments offered by the two parties to the controversy, and he found that it was a situation in which indeed "experience was fallacious and judgment difficult"; on the one hand it was asserted by the foresters that floods were steadily on the increase in the rivers of North America and of Europe, and that this increasing flood frequency was the consequence of deforestation on the watersheds and in the basins of these rivers. It was therefore urged by the foresters that the cutting away of the forests about the headwaters of the rivers should cease, and that an attempt should be made to reforest the areas that had already been denuded. On the other hand the engineers and meteorologists who had adopted the modern views asserted that the figures presented by the foresters were misleading, and in support of their statements offered other observations made upon the same rivers at the same stations to prove that floods were neither more frequent nor more severe than in former times. Consequently, there being no change in the flow of the rivers, deforestation could have no such injurious effect as they had been taught to attribute to it.

Further, it was claimed that all forested land which had been converted into agricultural land had been put to its best use and that no land which was suitable for the growing of crops to provide food for the people should be withheld for the growing of timber. It was of interest to note that this last view was shared by many, even of those who believed that forests were an important agency in regulating the flow of streams and surface water. The speaker did not attempt to reconcile the apparently conflicting data offered by the foresters on the one hand and by the engineers on the other. To show the difficulties of the situation he briefly referred to two publications, one by the French engineer, Belgrand, the other by Pierre Buffault. These were contradictory reports. The speaker had been hopelessly confused by the claims and statements of the two sides until quite recently; now he thought he saw a new light and would present a few conclusions for consideration. The forest floor surely protected the springs and controlled the surface flow of water better than ground that had been denuded of its natural cover, especially if it lay upon the hill or mountain side. If, however, the ground was fairly level and was suitable for agriculture and was under constant cultivation, the growing crops formed not a bad substitute for the forest. One should agree with Raphael Zon that "the fundamental principle upon which a wise national land policy should rest was that every acre of land should be put to the use under which it would bring the highest returns." One should not expect to reforest level or slightly rolling land which was now under cultivation, nor should one consider it advisable to do so. Practically all forested land which would serve for growing food crops would eventually be cleared for that purpose. In the mountain ranges, on the other hand, and upon steep hillsides the forests should be preserved, not only to insure a regular supply of water for great river systems, but also to prevent the danger of excessive erosion.

The Climatic and Hygienic Influences of Forest Growth.—By Dr. James M. Anders of Philadelphia. (See page 659.)

Professor Stupart of Toronto said that some years ago he undertook an investigation of the rainfall occurring along the Great Lakes of North America and other places, from which he concluded that, so far as he could judge, the rainfall to-day did not equal that of the earlier days, in 1840. With regard to the temperature since 1840 at Toronto it was fairly evident that the summer in Toronto to-day was but slightly increased—the spring months were not quite as cold as during the early years. With regard to the investigations regarding the winter temperatures it was shown that the ideas of the old inhabitants were erroneous; they believed that the winters some seventy years ago were colder than now; in 1840 in Toronto the temperature was 25.5°, while last year it was 23.4°. The daily range of the temperature to-day was probably the same as seventy years ago. The figures given from Montreal went back to 1873 and beyond; in the sixties the rainfall was 38 inches; during the next ten years 39.2, and then on it averaged 41.4, 41.7, etc. There was certainly an increase. It appeared that, so far as the meteorological records were concerned in Canada, the operations of man had but little effect upon the climate of the country. The speaker could not account for the greater liability of the summer frosts in the early days in Canada. The phenomenon of the great rainfalls was connected with the operations of Nature. In Canada and in the United States the rainfalls were of cyclonic origin. The forests had an inappreciable effect upon the amount of moisture which followed. The greater part of the rain which fell over the northern part of the United States and Canada was formed from the moisture brought from the Atlantic and the Gulf of Mexico. Floods to-day were no more disastrous in Canada than they were during the early years. In Canada they had snow until March and early April; the snow in the woods he believed must have some effect on floods. The rainfall occurring under such conditions would cause a rapid melting of the snow and this, of course, would lead to floods. However, if the snow fell in the wooded lands, in the early spring, there would be a gradual wasting away.

Dr. J. H. Elliott of Toronto, Canada, said that the question of deforestation was beginning to play a very important part in Canada as well as in the United States. The theory of Dr. Anders that forests modified the temperature seemed to be excellently borne out by facts presented by Professor Stupart.

Dr. Charles L. Minor of Asheville, N. C., said that it was not a question only of how deforestation affected the rainfall, but it was a question whether deforestation exerted a harmful effect on the flow of water in the

rivers and the water supply in the low-lying countries, causing water freshets and washouts. It all differed in different parts of the country. In North Carolina, with mountains ranging from 2,000 to 7,000 feet, with high hillsides, one could realize that if the hills were stripped they would practically be useless for other purposes.

Dr. William H. Bergtold of Denver, Col., said he had been in the Rockies for about thirty years and the conditions there were parallel to what Dr. Minor had described except that they were more accentuated. The question of deforestation and of the increase or decrease of floods was a complex one. In Wyoming, Colorado, and New Mexico so much water was used for irrigation that it was impossible to say to-day whether the streams were higher than in corresponding periods years ago. However, he did not believe their floods were higher to-day than they were forty or fifty years ago.

Dr. Alexander D. Blackader of Montreal said the value of any health resort should be estimated by both the amount of sunlight and of shade. One would not say that the presence of many trees was not conducive to health; however, where timber predominated and where sunlight seldom entered noxious influences were at work.

Dr. A. J. Richer of Ste. Agathe des Monts, Province of Quebec, told of the consumptives that were living in a lumber camp with the temperature 40° below zero and said that he was impressed with the extreme comfort in which they lived, without any of the advantages of real household living; there was a form of primitive life and the degree of comfort enjoyed by them appeared to be marvelous. There seemed to be some vitalizing influence.

Dr. J. Madison Taylor of Philadelphia said that in the discussion so far they were not looking close enough to the comparison of conditions to get a proper degree of the sense or knowledge in respect to the conditions that existed in the ancient countries where the forests had ceased to exist. They should take into consideration and present in a parallel way with what now existed the conditions that existed in Greece, in Mexico, and in the valley of the Euphrates. He thought that the whole subject was bound closely with another, anthropology; these subjects were more or less interwoven; the lines for research were closely associated. He called attention to Woodruff's article on "Expansion of the Races," which pointed out lines along which it was desirable to conduct investigation.

Dr. Guy Hinsdale of Hot Springs, Va., referring to Dr. Anders' remarks on ozone and to its great value, said that there had been some doubt raised as to its real value and the part it played. There was some doubt as to the accuracy of the test for ozone, and he would suggest that they should take up the real relation of ozone and the conditions concerning health.

Dr. James M. Anders of Philadelphia believed that stations should be thrown out in various places beyond the borders of the forests. There was no doubt that forests possessed certain influences in reference to the temperature and relative humidity, but he did not know how far this influence extended beyond the borders. As to whether the observations in reference to ozone might be conclusive or not, he confessed he could not say that the position taken was tenable. He had followed the usually recognized tests. He used glass cases which did not permit the entrance of the outside air. The results were uniform; certain species seemed to possess the power of producing ozone, even the nonodorous plants. His belief was that the balance of testimony was in favor of the flowering plant and odorous plant producing ozone.

A Résumé of the Opinions Upon the Nauheim Treatment of Chronic Diseases of the Heart.—Dr. John M. Swan of Glen Springs, Watkins, N. Y., read this paper. He said that his attention during the past year had been called to the criticism of the Nauheim method of treatment of cases of chronic heart disease contained in Mackenzie's book. After reading Mackenzie's statements over carefully he thought it might be valuable to review the books written on the subject of cardiac disease, in order to determine the opinions held by various writers concerning the efficiency of this form of treatment. All of the writers, except Mackenzie, conceded the benefit to be derived by a course of hydrotherapeutic treatment of a suitable case of chronic heart disease. Allbutt was opposed to its use in cases of "overstress of the heart" or heart strain, and Mott was opposed to its use in cases of angina pectoris and arteriosclerosis. The important point to determine was whether an individual case was a suitable one for the treatment. Mackenzie questioned the influence of the Nauheim baths on blood-pressure, referring to the statement made by the Nauheim physicians that the baths would raise a low blood-pressure and lower a high blood-pressure. In prescribing hydrotherapeutic measures the only method to be recommended was that which should be followed in prescribing any other form of treatment; to make a careful study of the case, its history, physical condition, urine, blood, pulse tracings, and then to prescribe the course of treatment which held out the most hope for ameliorating the condition found. Mackenzie stated that the same effect could be obtained by fresh water baths as by brine baths. The speaker had just begun a series of observations by which he hoped to be able to throw some light upon this subject. He was confident, however, that there was more to be accomplished by the use of carbonated brine baths and resistance exercises than could be accounted for by the mental effect. He was sure that these measures produced definite physical benefit in persons who had serious organic heart disease. Many patients had been sent to health resorts for "Nauheim" baths when such a treatment was not suited to them. By the term "Nauheim bath" he meant a cold brine bath in which free carbon dioxide was liberated. He urged the abandonment of the term "Nauheim" and the substitution of the term "brine" for these baths. The assembling of neurotic people in crowds was a bad feature; patients could not be stopped from detailing their symptoms to anyone who would listen. How these baths produced their effects was not definitely known. The speaker believed that the treatment was a purely empirical one. The most important effect was the equalization of the distribution of the blood in the skin and viscera by the vasodilation produced in the cutaneous vessels. He did not believe that the unbroken skin would allow the passage of gas and salts. The sanatorium régime in the treatment of chronic heart disease, which régime included rest, diet, hydrotherapeutic and mechanotherapeutic measures of various kinds, was productive of benefit. The carbonated brine baths in suitable cases did good by evening up the circulation through a dilatation of the cutaneous vessels, thereby relieving the peripheral resistance to the heart's work. He believed the treatment to be indicated in cases of cardiac weakness following the acute infections, accompanying debilitating and wasting diseases, following severe hemorrhages and the secondary anemias, and following surgical operations; in the early cases of failure of compensation in chronic valvulitis; in cases of simple dilatation; in cases of cardiac neurosis, and in cases of tachycardia and arrhythmia. The treatment was contraindicated in cases of nephritis, aneurysm, advanced arteriosclerosis, and in severe cases of broken compensation with edema. In early cases of fibroid myocarditis with high blood-pressure and beginning arteriosclerosis the baths, if given at all, should be given with great caution.

Dr. James M. Anders of Philadelphia thought that it

was unfortunate that the Neuheim method was not something more definite than it appeared to be at the present day in the literature. It should be kept clearly in mind that the Nauheim and the Shott methods were not synonymous. The majority of practitioners combined the Nauheim baths with resistance exercises. At the present day the tendency was more and more to individualize the cases. In other words, there was no single method of treatment for cardiovascular diseases as applied at Nauheim, but there was a treatment for individual cases. With neurasthenic patients the speaker had seen the Nauheim baths, plus the resistance exercises, cause patients to have sleepless nights. The resistance exercises practised alone were particularly beneficial when the myocardium was weak. In aortic incompetency the Nauheim baths were contraindicated. However, resistance exercises, if carried on carefully, often proved of the greatest service. In simple dilatation of the heart as the result of overstrain, in mitral regurgitant and mitral stenotic conditions, particularly during the early stages when there were a slight edema and dyspnea, in the early stages of arteriosclerosis the Schott method, so-called, gave brilliant results. Of course something must be attributed to a salubrious climate, to environment, etc. Many patients were sent to Nauheim that were not suitable for the treatment; of course they received no benefit. The question naturally arose with them whether the home use of the Nauheim baths could be made efficient; personally he did not think it would, because patients then remained in their customary environment, they were not freed from their worries and business anxieties. It was better to send these patients away from home, but not so far as abroad.

Dr. Egbert Le Fevre of New York said that there were practically three stages of arteriosclerosis. First, where the cardiac power was in excess, a cardiac hypertrophy with a high tension pulse. Here the pressure was largely due to disease of the blood-vessels and vascular control. In such cases carbon dioxide baths with resistance exercises had no place. Then there was the stage in which the reserve cardiac power was diminished; in this stage the anginoid attacks appeared. There appeared, too, a second factor, a spasm of the peripheral blood-vessels which raised the blood-pressure. In these cases the Nauheim baths and the carbon dioxide baths, associated with resistance exercises, were beneficial. In the third phase of the arteriosclerotic type of disease there was a permanent loss of cardiac power; this was called the asphyxia stage, and the only way to equalize the circulation was through the vasomotor system. In such cases there was a call for a higher pressure, nature's method of increasing the circulation. In the failing or failed heart the carbon dioxide baths only added to the burden.

Dr. Joseph H. Lowman of Cleveland, Ohio, believed that much could be done with the resistance exercises by the general practitioner, especially in the convalescing patient. The time the patient was compelled to lie in bed after an endocarditis, after pneumonia, and many other diseases was much diminished by graduated exercises. But the resistance exercises should not be begun first, and especially in those with feeble hearts. Passive exercises should come first.

Dr. John M. Swan of Watkins, N. Y., acknowledged that there was much ignorance abroad concerning the subject under discussion. The term "Nauheim" as used in this country was a misnomer. The best results were obtained by giving a series of baths and then giving resistance exercises after the baths had been discontinued.

The Causes of Death in Pulmonary Tuberculosis.—Dr. Lawrason Brown of Saranac Lake said that recent advances in the study of tuberculous infections clothed with fresh interest even the causes of death in chronic tuberculosis and lent to the study of their failures the hope that here also they might gain some knowledge to aid in the further struggle against this disease. Death in chronic tuberculosis was brought about most often through pathological changes in the lungs, less often by those occurring in the heart or brain. This study of the causes of death in chronic pulmonary tuberculosis was based on data obtained from the records of death of 1204 patients who had died at or after leaving the Adirondack Sanatorium, and from 378 deaths which had occurred in Saranac Lake Village. For various reasons it was impossible to obtain reliable data concerning 245 patients; this limited the study to 959 deaths. While the usual cause of death in chronic pulmonary tuberculosis was asthenia, the complications which terminated life were very numerous and might be grouped under four heads: (1) general miliary tuberculosis, (2) pulmonary, (3) extrapulmonary complications and (4) sudden death. It was comparatively easy to arrange such a classification, but most difficult to fit cases into it. Asthenia and asphyxia were really functional conditions or states. The classification of the causes of death in chronic pulmonary tuberculosis was presented as follows: A. Death associated with marked functional changes. (1) Asthenia, usual cause of death. (2) Asphyxia. B. Death associated with marked pronounced pathological complications. (1) General miliary tuberculosis. (2) Pulmonary conditions, hemoptysis, pleurisy, gangrene, pneumothorax, pneumonia (lobar), empyema, generalized subcutaneous emphysema. C. Extrapulmonary complications. (1) Meningitis, tuberculosis of the brain, laryngitis, enteritis, pericarditis, nephritis, Addison's disease, peritonitis, tuberculous obstruction of the intestines, spondylitis, and coxitis. (2) Circulatory conditions: Syncope, thrombosis and embolism of the pulmonary artery, heart disease, nephritis, diabetes, cancer, appendicitis, accident, suicide, typhoid fever, lymphatic leucemia, meningitis, cerebral abscess, sinus thrombosis, senile dementia, etc. In all 332 patients (58 per cent.)—163 males and 169 females—presented asthenia as the most marked symptom before death. It was of interest to note that twenty-eight patients died from asthenia following hemoptysis, of whom nineteen were men. Immediate death from hemoptysis occurred in eighty-two patients. Symptoms of enteritis occurred in thirteen women and in only five men. Symptoms of nephritis were present in fourteen patients. Asphyxia was described as the most marked cause of death in twenty-one cases. Pulmonary tuberculosis was stated as the only cause of death in 385 instances. Profuse sudden hemoptysis in the earlier stages of the disease was an unusual cause of death; when it occurred it was brought about more often by suffocation. Fatal hemoptyses were in practically every instance due to a rupture of an aneurysm of one of the terminal branches of the pulmonary artery. Death from pneumothorax occurred in three of the reported cases. Gangrene as a cause of death was exceedingly rare. Death due to extrapulmonary causes occurred in 111 cases. Syncope was given as a cause of death in thirty patients. Sudden death in pulmonary tuberculosis was unusual. A point that suggested itself in the study of the causes of death in a chronic disease like pulmonary tuberculosis was whether or not Osler's dictum that a patient rarely died of the disease from which he suffered held true. It was of interest to glance over the forty-four deaths that had occurred among the 3,300 patients during their residence at the Adirondack Cottage Sanatorium. Of these forty-four, thirty died with signs of pulmonary disease, eight of extrapulmonary tuberculous complications, and six of non-tuberculous diseases. The figures that related to the 378 patients who died at Saranac Lake from pulmonary tuberculosis showed that 256 died from asthenia, four from

asphyxia, fourteen from general miliary tuberculosis, forty-eight from hemoptysis, eight from pneumothorax, twenty-two from meningitis, ten from laryngitis, etc.

Dr. H. R. M. Landis of Philadelphia said that some years ago he made a study of seventy-five cases of death in pulmonary tuberculosis and he found that most of these died of general asthenia or because of a ceasing function. Three of the patients died from intestinal hemorrhage. It was amazing that so few cases died of complications referable to the gastrointestinal tract. So far as his observation went asphyxia in tuberculosis practically never occurred. Out of 600 cases not one died suddenly from heart failure; this was a rare form of death in this disease.

Dr. J. H. Elliott of Toronto, Canada, said that pneumothorax was very frequently overlooked by the general practitioner. During the past year he had seen three cases in consultation, and in none was the diagnosis made by the physician. In these cases asphyxia would probably be given as the cause of death.

The Class Method in the Treatment of Pulmonary Tuberculosis.—Dr. Joseph H. Pratt of Boston told of what he had tried to do and what he had accomplished by sanitary methods among the poor people who came to the Massachusetts General Hospital. He started a tuberculosis class in 1905, getting his financial support from the Emmanuel Church; in fact, during the past six years the expenses had been born by this church. The methods of treatment employed were probably familiar to all. Of course they met with some failures. Those who were improved returned to work. They had the homes visited by nurses and once a week the speaker saw all the patients under his care. Facilities for outdoor life were afforded. He found that it was easy to control patients and, if necessary, to keep them in bed; what he emphasized was the importance of absolute rest in bed; as soon as they gave the patients liberty regarding exercise recovery was often retarded. During six years they had had 117 patients, all selected. Of these sixty-four recovered. There were but three relapses. Two deaths occurred among those who were discharged when the disease was arrested, both being women, and during the pregnant state the disease returned and ran a rapid course. Twenty-five were admitted in the first stage of the disease and all recovered. Among those in the advanced stage of the disease ten were arrested and eighteen died. It was not easy to maintain supervision over these patients. The social aspects regarding pulmonary tuberculosis were important. The study of the treatment was an educational one and benefited the patients very much. The class method of treatment of pulmonary tuberculosis in New York City had been productive of excellent results, as it had been in Honolulu, Belfast, and other places. The climate of Ireland was more unfavorable in the treatment of pulmonary tuberculosis than that of England. He believed that the home treatment of these patients had advantages over the sanatorium treatment; if the patients got well under the home treatment they were more apt to remain so. The patients took a cold bath in the morning and drank from one to two quarts of milk a day.

Dr. Charles L. Minor of Asheville, N. C., believed that the most important feature of the class method was, in comparison with other methods, the broadening of the personal relation between the doctor and his patient. That was really the essential thing and was really the keynote to success.

Wednesday, June 14—Second Day.

On the Recording of Physical Findings in the Lungs, with a Scheme of Notation Therefor.—Dr. Charles L. Minor of Asheville, N. C., described the system he had used, illustrating it on the blackboard.

A Retrospect: A Few Thoughts and Suggestions Based upon Twenty-five Years' Experience with Tuberculosis.—Dr. Vincent Y. Bowditch of Boston read this paper. (See Medical Record, August 5, 1911, page 291).

The Economic Value of the Sanatorium Treatment of Pulmonary Tuberculosis.—Dr. David Russell Lyman of Wallingford, Conn., read this paper, the object of which was to set forth the economic return to any given community from money invested in the treatment of its cases of pulmonary tuberculosis by modern sanatorium methods. The Gaylord Farm Sanatorium was opened Sept. 20, 1904, and on May 1, 1911, they had discharged 676 cases who had been away from the institution six months and over. They could claim a high percentage of accuracy for their records. However, 34 were school children and, having no earning capacity, were omitted. This left 633 cases on which the studies were based. One table presented covered 140 incipient cases, 373 moderately advanced cases, and 120 far advanced cases. It was of especial interest in that it bore out the fact so often insisted upon that the results of treatment were in direct ratio to the stage of the disease at which the diagnosis was made. The incipient cases showed average total earnings of $1,020.60, the moderately advanced of $842,22, while the far advanced had earned on an average but $192.10. The same ratio held good in the relation of the "weeks of work" to the "weeks of life" in the several cases. The incipient cases showed a working capacity of 70 per cent. of their total time since discharge; the moderately advanced 59 per cent., and the far advanced only 23 per cent. The average weekly wages varied but little for the three classes. In another table presented the cases were classified according to the condition on discharge. In this table they dealt with 262 cases discharged "arrested," 253 "improved," and 118 "progressive." The arrested showed average total earnings of $1,039.48; the improved, $719.53; the progressive only $72.55. The percentage of "weeks of work" to "weeks of life" was 67 per cent. for the arrested, 47 per cent. for the improved, and 14 per cent. for the progressive. Table 3 showed the total earnings of all patients and the relation between this sum and the amount expended on the sanatorium. This showed a total expenditure of $236,744.51, whereas the amount already earned by discharged patients was $464,406.00, a return of about 200 per cent. within six years from the commencement of the work.

The Ventilation of Hospitals and Schools.—Dr. John Winters Brannan of New York presented this subject, which he illustrated with lantern slides. In planning the ventilation of hospitals and schools he said their aim should be to give both patients and school children air that was approximately as pure as that outdoors. Both hospital and school air should be standards of purity instead of being, as was usually the case, of various grades of impurity. The typical hospital ward was long and narrow, with the two long sides and one end freely exposed so as to secure the maximum of light, air, and sunshine. The windows and transoms on the long sides placed opposite to each other the entire length of the ward were admirably arranged to give cross ventilation. Often the windows seemed to be regarded simply as means to secure light; their function of permitting the entrance of fresh air was largely neglected. Architects and engineers devised elaborate plans for ventilation which were unnecessary if the ward was properly designed and the windows and transoms were properly used. In the medical pavilions of the new Bellevue Hospital, which were opened some three years ago, a complete modern ventilating plant was provided; this system had not been found satisfactory in operation, and during the past winter it had been entirely discontinued and the air in the wards

was simply warmed by the radiators and kept fresh and pure by open transoms, supplemented by open windows when necessary. The temperature in the ward was kept at 65° or less during the day and at 60° or less during the night. On entering a ward with the temperature between 60° and 65° one felt a freshness and exhilaration of the air that were totally absent in a ward ventilated and warmed by an artificial system of ducts and fans. The experience had been the same in Gouverneur, Harlem, and Fordham Hospitals, in all of which similar ventilating plants were installed and had been found unnecessary and had been discontinued. Profiting by this experience, they had provided a much simpler system of ventilation in the plans for the surgical pavilions of the new Bellevue Hospital which were about to be constructed. There was to be no warmed, filtered, and moistened air forced into the wards by means of fans and ducts. There were, however, to be exhaust flues to aid in the exit of foul air, with fans to draw the air upward and out. It was probable that hot coils in these flues would accomplish the purpose of drawing the air out. The speaker said he would like to see absolutely natural ventilation tried in the hospitals, with the exception of the operating rooms. The ventilation of the schoolroom was more difficult than that of the hospital ward, as the room had usually windows only on one side. There should be a transom over the door to allow the air in the room to pass freely between it and the corridor. The corridors should have windows at each end. Pivoted windows kept the air in the schoolroom fresh and pure at all times, and without drafts. The ventilation in practically all of the public school buildings of New York was very imperfect.

What Is a Tuberculosis Sanatorium?—Dr. Edward O. Otis of Boston presented the following questions: (1) In order to have a true tuberculosis sanatorium, must it receive only incipient cases? (2) Could it be regarded as such if, in addition to incipient cases, it received those moderately advanced or advanced if they presented possibilities of cure? (3) Must it be situated in a region with especially favorable climatic elements? (4) Could it be considered a sanatorium if advanced or hopeless cases were received? (5) What was the best method of selecting suitable cases for the sanatorium, or could this be done under any method of selection? (6) In a State or public institution was it practically possible to obtain all early or curable cases, and should such an attempt be abandoned? (7) Was it objectionable to receive into the same institution called a sanatorium the hopeless cases as well as the early or curable ones? (8) What distinction should be made, if any, between a sanatorium and a consumptive hospital?

The Relation of Tuberculosis to Chorea, Hyperthyroidism and Pharyngeal Hyperplasia.—Dr. Charles Miner of Wilkes-Barre, Pa., said that his interest in these relations had been aroused by the work at the State Tuberculosis Dispensary at Wilkes-Barre, where they had examined many children of tuberculous parents, and among them had found conditions present which seemed in some way related to the tuberculous infection they had contracted. They found a large number with chorea, or with a history of having had choreic symptoms; again among the older members of the families they found a number with the signs and symptoms of hyperthyroidism; finally they found a very large number with pharyngeal hyperplasia. The speaker said that the invasion of the tubercle bacillus was often a slow process, and the significance of tuberculosis in childhood was not limited to the disease itself, but by lowering the tone and resistance of the child it led to the development of abnormal conditions and other infections. They could not prove that chorea, hyperthyroidism, and pharyngeal hyperplasia found in tuberculous children and young adults were caused by the tuberculous infection, but the knowledge of their frequent association might lead, through further investigation, to the discovery of some definite relation of tuberculosis to these conditions.

Studies of the Leucocytes in Pulmonary Tuberculosis and Pneumonia.—Drs. James Alex. Miller and Margaret A. Reed of New York presented this communication. It had long been recognized that the leucocytes of the circulating blood played an important rôle in many if not all of the infections. The researches of Arneth, calling attention to the morphology of the nucleus of the neutrophile, especially in tuberculosis, had stimulated further studies in this direction. The results reported were often suggested by the work of Arneth and represented effort to corroborate and amplify those results by various experimental and clinical observations, and especially to determine their value in the diagnosis and prognosis of pulmonary tuberculosis and pneumonia. It seemed possible that Arneth had laid undue emphasis upon the significance of the neutrophile leucocytes and that it was important to study the other forms of leucocytes in connection with them. Pneumonia was chosen as a companion study with pulmonary tuberculosis as forming a contrast of an acute with a chronic pulmonary disease. The speakers concluded as follows: (1) The study of the leucocytes gave reliable information in the prognosis and clinical course of pulmonary tuberculosis. (2) In the diagnosis of incipient cases it was of no assistance; but in the differential diagnosis of acute pulmonary lesions due to the tubercle bacilli or to some other infection it was sometimes helpful. (3) Arneth's differential neutrophile count was important in tuberculosis. In pneumonia, while the shift of the blood picture occurred regularly, it had no constant relationship to the course of the disease. (4) In general the following changes in the leucocytes occurred in cases of pulmonary tuberculosis which were progressively doing badly, or during an exacerbation of the disease: a leucocytosis; an increased percentage of neutrophiles; a diminished percentage of small lymphocytes; a diminished percentage of eosinophiles; a marked shifting to the left of Arneth's blood picture; conversely, changes in the opposite direction were favorable. (5) In pneumonia their observations had made no material contribution to their knowledge of the behavior of the leucocytes.

Atypical Pneumonia.—Dr. Jay Perkins of Providence, R. I., said that under this heading he had chosen to include those cases of pneumonia the specific organism of which was not known. It thus practically included all cases of pneumonia except those produced by the pneumococcus and the tubercle bacillus and included cases of mixed infection even when these organisms were present. His paper was suggested by the paucity of literature on such cases and the error frequently made in diagnosing them as tuberculosis. Atypical pneumonia was more insidious in its onset than croupous pneumonia, unless caused by some infection secondary to a pneumococcus infection. These pneumonias were seen in the aged, in alcoholics and as postoperative sequelæ, as associated with typhoid fever, with heart disease, with nephritis, in the tuberculous, or in any condition in which the natural resistance of the body had been lessened, although it might occur in strong individuals as well as in the weakened ones. In atypical pneumonia, as compared with pneumococcus pneumonia, the fever lasted much longer, the termination was by lysis, or in abscess formation, or chronic pneumonia, or other secondary pathological conditions of the lungs, and there were complications not met with in pure pneumococcus pneumonia. In its onset a chill was not unusual, there was more likely to be a prodromal stage, the temperature was not so regular,

usually not so high, herpes labialis was absent, the spleen was frequently enlarged, and the disease was more likely to be of epidemic form. No regular course of atypical pneumonia could be given because, as the name "atypical" indicated, there was no regular course. In time, however, he believed that improved methods of diagnosis might remove many of these cases from the category of atypical pneumonia.

Physical Exercise and Blood-Pressure.—Dr. EDWARD O. OTIS of Boston said his attention was first called to this subject while making a physical examination of members of a large men's gymnasium. The men were young or middle-aged and the majority of them were engaged in indoor sedentary occupations. It occurred to him that perhaps, by means of the systolic blood-pressure, taken at three periods, namely, just before, immediately after, and then a little later, after a short rest or after the usual bath, he could thereby obtain some definite idea of the effect of the exercise in each individual case and thus have some practical guide as to the amount and severity of the work best suited to each person. Even the ordinary class work arranged for the average individual might be too severe for some and, consequently, defeat the purpose for which it was taken, namely, as a recreative measure. Of course he recognized that other elements besides the blood-pressure entered into the problem. He accordingly took the maximum blood-pressure at the three periods mentioned of 59 men, 6 boys, and 32 young women. In addition he took the blood-pressure of the first two periods, just before and immediately after exercise, of 29 men, making altogether rather over 350 separate measurements. In all the investigations, those of his own and others, practically the same results had been obtained as regards the variations of the blood-pressure before, during, and after exercise, depending upon the character, length, and intensity of the exercise. In brief, after prolonged and severe exertion there was a diminution of blood-pressure from the normal at the conclusion of the effort. After a short period of mild or moderately severe exercise, as in class work, the blood-pressure taken immediately at the conclusion of the exercise showed, in the majority of the cases, a rise, followed quickly by a fall to or near the normal or to subnormal. In his 126 cases of moderate general exercise 97, or 77 per cent., showed a rise of blood-pressure immediately after the exercise. In 9, or 8.1 per cent., there was no difference between the first and second measurement, and in 20 cases, or 16 per cent., there was a fall in the second measurement. To formulate the results he had obtained, as well as those of other investigators, one might say that physical exercise in the majority of the cases, of whatever nature it might be, excessive, long and continued, or more gentle and moderate, caused a rise in the systolic blood-pressure, the maximum occurring some time during the effort. As fatigue set in and advanced the pressure fell to normal or subnormal. If immediately after exercise the blood pressure was subnormal and remained so for some time, as in the case of the Marathon runners and football players, then for that individual, or for his condition at the time of taking the exercise, he might consider it too strenuous or too prolonged. Blood-pressure measurements might be applied to workingmen if thereby one might more accurately determine their fatigue point, apportion their work accordingly, and thus both conserve their energy and obtain their maximum efficiency.

The Dust Menace and Municipal Diseases.—Dr. HOWARD S. ANDERS of Philadelphia said that of the causes of what might not inappropriately be termed municipal diseases, mostly obvious, some subtle in their workings, infectious irritation and neurovascular lesions played a predominant part. To specify three concrete elements corresponding to and mainly responsible for these etiological processes, there were dust, smoke, and unnecessary noises, and the one that loomed largest in municipal morbidity and mortality was undoubtedly the widespread prevalence of an irritating, as well as an infecting, dust contamination of the city atmosphere. This dust menace and nuisance was preventable, not only in the streets, as was now demonstrated in a few of the large cities, but likewise in the living and working places. There was in fact a vicious circle when street dust was blown, swept, and tracked into habitations, to be swept back into the streets again. Much house dust pollution would be avoided if the original street dust were removed or allayed. Dr. George A. Soper of New York stated: "There is something incongruous about a Board of Health conducting a crusade against smoke and noise and, at the same time, allowing the streets to be filthy with dirt and dust." Now that for about seven years street dust as an element in the propagation of disease especially in the large cities had received such marked and spreading recognition, the problem of street cleaning, as well as of housecleaning, was a live and urgent one. Modern civilization being mainly materialistic and commercialistic was responsible for the creation of a multifarious, mixed, material refuse. Street dust was such a pernicious and persistent menace to the public health because it bodied itself forth a veritable synthetic pulverized compound of various more or less palpable particles of mechanical, chemical, and bacteriological substances, both irritating and infective when inhaled. Apart from the modicum of the mineral dust from the wear and tear of street pavements by horse, wagon, and railway car traffic, municipal dust represented the accumulation of débris of various kinds, animal and vegetable, such as dried sputum of human origin, horse and dog droppings and slobberings, dead and disintegrating insects, scattered garbage and house sweepings, loaded vehicle losses, smoke and soot, in short, mainly an organic combination which in warm weather was seething with rottenness; and in dry weather was mostly blown into houses, noses, and clothing by gusty winds, or sucked up as noxious, stifling clouds by automobiles and trolley-cars. To the average pedestrian dust was hardly more than an annoyance; hence the large opportunity and high duty of men in the medical profession to educate the public to the dangers of dust. For many years they had before them the deadly relation of the dust evil to tuberculosis; this alone should justify the fight for street cleanliness and a declaration of independence against dust distributors. But when one added to this the host of other dust-borne diseases, catarrhal, tonsillar, bronchial, influenzal, pneumococcic, rheumatic, cutaneous, etc., the need of efficient public service in remedying and removing the evil became intensely imperative, and the demand inexorable for right results. Most of the so-called "colds" were dust infections gotten in places where people congregated and traffic circulated freely. Human agency was principally at fault in polluting the air with disease-bearing dust and human agency and energy must be solicited and directed to arrest, subdue, and prevent its production and propagation. The so-called air-borne diseases of the great cities were really synonymous with dust-borne. The speaker told of the agitation against the dust menace in Philadelphia and of the results they had obtained; while to-day far from satisfactory, substantial improvement had been brought about. Circular letters of inquiry were sent to the mayors of some twenty-five cities of America and Europe as to the methods and results of cleaning streets and keeping them clean; in summarizing the results of these inquiries the speaker gave the following: (1) Thorough sprinkling before sweeping; sprinkling also done two to four times in dry (non-freezing) weather to

settle prevalent dust. (2) In the majority of the cities where the results were satisfactory the principal cleaning was done at night, or completed before six o'clock in the morning. (3) Flushing wagons or flushing from curb to curb with hose were used in preference to sprinkling and machine sweeping in the best cleaned cities. Indeed, sprinkling was seldom necessary where the streets were thus virtually washed two or three times weekly. (4) Hand sweeping by blockmen in daytime was always preceded by wetting with a hand sprinkler. (5) Immediate removal of the piles of dirt while wet in covered wagons. (6) Last but by no means least, and the method which, in the speaker's judgment, was destined before long to supersede all others in street cleaning, was the dustless operation of automobile vacuum street cleaners.

THE AMERICAN DERMATOLOGICAL ASSOCIATION.

Thirty-fifth Annual Meeting, Held at the Hotel Lenox, Boston, Mass., May 25, 26 and 27, 1911.

The President, Dr. Douglas W. Montgomery of San Francisco, in the Chair.

Thursday, May 25—First Day.

President's Address.—Dr. Montgomery, in his opening address, said the great subject of serology was now engaging a just measure of attention, and promised to give one a teleological insight into disease that had never been obtained before. The discoveries of the attributes of the sera of the body gave one a tangible, scientific insight into what had been vaguely designated as the patient's constitution, and it was probable that the phenomena of anaphylaxis would elucidate many of the eccentricities of diseases, such as eczema. Many now believed that eczema was merely a peculiar irritability of the skin that might be excited by various stimulants. The real riddle lay in bringing to light why a person would get an eczema under an irritation that had no detrimental effect whatever on almost anyone else, and that not at all times would the same irritant cause an eczema in the same person. This susceptibility or vulnerability of the skin was ascribed to the patient's constitution, and attempts were made to classify patients as having this or that diathesis. Now, both the matter of constitution and also the effects of foods and drugs were placed in a different light by the investigation of the bacterial toxins, and the curious reactions of the blood both to toxins and to normal albumins, such as serum, red blood corpuscles, and egg white. One now seemed to be in a fair way to know something about the constitution.

Sarcoid Tumors of the Skin, with Report of a Case of the Boeck Type.—Drs. George H. Fox and Udo J. Wile of New York stated that under the name of sarcoid tumors Kaposi provisionally grouped mycosis fungoides, lymphodermia perniciosa, and sarcomatosis cutis, his object being to point out the nosological relation between sarcoid and certain granulomata of probable infectious origin. Others adopted the same name, but restricted it to a group of neoplasms composed of round cells, and characterized by a limited growth and comparative benignancy. In 1899 Boeck published in the *Journal of Cutaneous and Genitourinary Diseases* a notable article entitled "Multiple Benign Sarcoid of the Skin," in which he reported a hitherto undescribed dermatosis for which he claimed characteristic and unmistakable clinical as well as histological features. Cases of identical or similar nature had been since reported by observers in various countries, and a rather extensive literature on the subject of this rare disease had already developed. In America the only cases reported were those of Pollitzer and Gottheil. In the Boeck type of sarcoid the lesions developed in the form of one or more large nodules, or occurred in the form of numerous papules or one or more infiltrated placques. It usually appeared on the face, back, shoulders and the external aspect of the arm. The patient's general health seemed to be but little affected, and the subjective symptoms were slight, if present at all. The tumors were firm and elastic, reddish or purplish in color, and showed delicate peripheral telangiectases and occasionally slight scaling. The course of the disease was chronic, and the lesions never ulcerated nor softened. When involution occurred, a central umbilication formed, with gradual flattening of the periphery until a pigmented area or slight atrophic scar remained. Dr. Fox then reported in detail a case of this type, in which the eruption persisted until a series of injections of arsenite of soda were given, when a notable improvement took place. A 4 per cent. solution was used, the dose being steadily increased from five to twenty minims, and then steadily decreased.

The Relationship of Vaccine Therapy to the Treatment of Certain Diseases of the Skin.—Dr. David King Smith of Toronto read a paper on this subject.

The Mottled Chin in Syphilis, and Other Dermatological Observations.—Dr. William B. Trimble of New York, in a paper with this title, discussed the following points: (1) The mottled chin in syphilis. In a number of cases of early syphilis, that is, during the first few weeks or months of the disease, the chin was marked with a macular, variegated eruption which was characteristic and identical in every case where it was present, varying only in degree. It was especially noticeable on that part of the chin in or near the commissure of the mouth. (2) The second observation was the frequent association of lichen pilaris with early syphilis. (3) The third point was the tendency of nitric acid to produce keloids or hypertrophic scars. (4) The effect of the Röntgen ray on lesions of the mucous membrane. This was a plea for the more frequent trial of the *x*-ray in cases of inoperable malignant disease of the tongue and mouth, and even in some cases that might be considered operable, but where total extirpation was necessary. (5) The last observation was that alcohol facilitated bleeding. The facility with which alcohol started or increased hemorrhage was observed while treating cases of acne by the curettage method. During this operation the tops of a number of papules were scraped off, followed by more or less bleeding. In one instance, after the bleeding had been checked, while wiping off the face with alcohol for cleansing and antiseptic purposes, it was noticed that all the bleeding points began afresh, and by merely brushing over the surface with a pledget of cotton saturated with alcohol they could be made to bleed almost at will. It was immediately divined that this phenomenon would be of benefit in cases where it was desired to increase bleeding, and it had been advantageously used in rosacea where scarification was practised.

Dr. William Allen Pusey of Chicago said that, in spite of the statement once made by Dr. Gilchrist that he considered it criminal to treat an epithelioma of the lower lip with *x*-rays, he had treated many such cases with the *x*-rays and he could corroborate Dr. Trimble's observation that superficial epitheliomata of the lower lip often yielded remarkably well to that treatment.

Dr. Montgomery said that in almost every case of epithelioma of the lower lip there was an accompanying seborrhea of the same region. The epithelioma must first be removed, and this certainly could be done in some cases by *x*-rays, but no matter how diverse the opinions or facts might be in regard to the treatment of the epithelioma of the lip with *x*-rays it was his opinion that they were an excellent remedy for the seborrhea, which was a precancerous condition of which the epithelioma itself was the result.

Dr. Jay F. Schamberg of Philadelphia thought that in

spite of the favorable results that had been reported one should use the *x*-rays very gingerly on the mucous membranes, and not at all in operable cancer.

Dr. James C. White of Boston said that, with regard to the production of keloid after the use of nitric acid, he had supposed that sulphuric acid was far more prone to produce such lesions than nitric acid. He had many times employed nitric acid as a local destructive agent, with or without the curette, as well as the acid nitrate of mercury, which was essentially the same thing, and he could not recall a single case of keloid produced by either of these agents.

Dr. Joseph Grindon of St. Louis said the acid nitrate of mercury had been a favorite application of his for many years, and he had never seen a keloid or large cicatricial lesion follow its use.

Dr. M. B. Hartzell of Philadelphia said that with regard to the use of the *x*-rays in epithelioma of the lower lip, with proper exposure, not too prolonged, favorable results frequently followed in selected cases. The mucous membranes were very sensitive to the *x*-rays, and for that reason short exposures were necessary.

Dr. Thomas C. Gilchrist of Baltimore said he was still willing to uphold the statement that it was criminal to use the *x*-rays in the treatment of epithelioma of the lower lip. In this condition one usually had early involvement of the glands, and these were not benefited by the *x*-rays. All cancers of the lips should be treated surgically, as every case required removal of the neighboring glands.

Dr. A. R. Robinson of New York said he had never yet been able to recognize a basal-celled carcinoma of the lower lip; all of his cases had been of the spindle-celled type. A rodent ulcer of the lower lip was unknown to him. As to the use of the *x*-rays in these cases, the speaker said he agreed with Dr. Gilchrist. He had always found that the *x*-rays only aggravated prickle-celled carcinoma; they were unreliable, and instead of acting as a destructive agent in these cases they rather stimulated them to increased growth.

Dr. Francis J. Shepherd of Montreal said he agreed with Dr. Gilchrist that it was criminal to treat a cancer of the lower lip in any other way but surgically, as in those cases the glands were almost invariably affected.

Dr. F. J. Leviseur of New York said the difference between the knife and the *x*-rays seemed to him to lie in the fact that one could easily control the former, while it was difficult to measure the latter.

Dr. Howard Fox of New York said he could bear out Dr. Trimble's statement that keloids might follow the application of nitric acid.

Dr. John A. Fordyce of New York said that during the past twenty years he had examined histologically many epitheliomata of the lip, and he had never seen a primary basal-celled epithelioma in this region. He agreed with Dr. Robinson that practically all of these epitheliomata of the lip were of the squamous-celled type, and he also believed that surgical treatment was the method of choice in these cases.

Dr. Trimble, in closing, said he agreed with both the surgeons and the dermatologists. If the case was operable surgical measures should be resorted to; if it was inoperable other measures had to be tried. Many of these patients refused operation, and in such a contingency some other method of treatment had to be found.

Dermatitis Vegetans in Infants.—Drs. Grover W. Wende and Herman K. DeGroat of Buffalo read this paper.

A Comparative Study of the Wassermann and Weil's Cobra Venom Reactions for Syphilis.—Dr. Hans J. Schwartz of New York reported the results of this work, which was undertaken at the suggestion of Dr. James C. Johnston. The author stated that a comparative study of the Wassermann and Weil's cobra venom reaction for syphilis carried on during the past year had brought out certain points which seemed to merit attention as indicating that Weil's reaction was a valuable adjunct to the Wassermann reaction in the diagnosis of syphilitic conditions. A study of the tables contained in the paper revealed: (1) That the Wassermann reaction was much more sensitive in the early, untreated stages of syphilis. In the primary stage the Wassermann gave a positive reaction in 73.9 per cent. of the cases; the Weil in only 54.3 per cent. In the early, active cases, with little or no treatment, the Wassermann was positive in 96.8 per cent.; the Weil in 67.1 per cent. In the early, latent cases with little treatment, the Wassermann was positive in 90.0 per cent.; the Weil in 75 per cent. (2) In the latter, untreated stages of the disease, the opposite conditions obtained, namely, the Weil was more sensitive than the Wassermann. In the late, active cases, with little or no treatment, the Wassermann was positive in 77.5 per cent.; the Weil in 81.6 per cent. In the late, latent untreated cases the Wassermann was positive in 34.7 per cent.; the Weil in 76.3 per cent. (3) In the treated cases it was found that the Weil reaction was much the more sensitive throughout; in other words, the Weil reaction persisted much longer after mercurialization, and therefore offered a further diagnostic and therapeutic test. In conclusion, the author stated that the Weil reaction seemed to be specific for syphilis with the sole exception of carcinoma. The Wassermann and the Weil reaction did not run parallel to each other, but one proved sensitive under conditions where the other failed. He therefore considered that the application of the two tests, both in the diagnosis and therapeusis of syphilis, was highly important.

The Results of the Wassermann Reaction in Sixty-one Cases of Syphilis Treated with Salvarsan.—Dr. Martin F. Engman and R. Buhman of St. Louis offered the following conclusions: (1) Of 61 cases, 32 received salvarsan alone; of these, none (28 per cent.) gave a negative reaction, and 23 (72 per cent.) gave a positive reaction. (2) Of the nine negative cases, two received two doses; therefore, only seven (21 per cent.) of the 32 became negative after one dose. (3) Of the group of persistent positives, five had two doses and one had three doses. (4) Of 61 cases, 29 received mercurial injections following the salvarsan, and of these fourteen (48 per cent.) gave a negative reaction. Four cases gave a persistent positive after two doses of salvarsan and mercurial injections. (5) Seven cases had two doses of salvarsan alone. Of these, only two (28 per cent.) became negative, while five remained persistently positive. These were all severe cases. (6) In the earlier syphilides salvarsan was used alone in six cases, with 33 per cent. of negative reactions. (7) In the later syphilides salvarsan was used alone in 26 cases, giving a negative reaction of 26 per cent. (8) Junkemann's method used in 43 cases gave a negative reaction in sixteen cases (37 per cent.), while 27 cases (63 per cent.) remained positive. (9) The intravenous method was used in sixteen cases with no negative after a single dose; two became negative after two doses, and five remained positive after two doses.

Dr. Howard Fox of New York thought it was difficult to draw any general conclusion as to the serological action of salvarsan, owing to the great discrepancies of different writers. A review of the literature showed that the proportion of negative reactions obtained ranged from 5 to 90 per cent. Most of the observations had thus far been made after a single injection, and it certainly seemed that one injection was an insufficient dose from the serological as well as the clinical standpoint. With regard to his own work, Dr. Fox said that 30 per cent. of the cases he had examined had changed from a positive to a negative

Wassermann reaction within six weeks after the administration of salvarsan. In general the action of salvarsan upon the Wassermann reaction was analogous to that of mercury. Every one would certainly agree that its action upon the clinical symptoms was much more rapid and marked than it was upon the Wassermann reaction.

Dr. R. Buhman of St. Louis said that, while the clinical symptoms following the injection of salvarsan seemed to subside very rapidly, the Wassermann reaction, without the aid of mercury, often remained strongly positive for some time.

Dr. E. Wood Ruggles of Rochester, N. Y., showed a small instrument which he had devised for the purpose of simplifying the puncture of the vein in giving injections of salvarsan, and also in obtaining blood for testing purposes.

Dr. William T. Corlett of Cleveland said that during a recent visit to medical centers in Europe he took occasion to investigate the work done, and had found that it was almost as indefinitely and carelessly done in Germany as in America, and the results were about the same. In Berlin a specimen of blood was sent to three different experts, one of them being Wassermann himself, and three different results were reported—one positive, one negative and one intermediate. It was claimed by those who had done the most work with the serum that the only place where the test was accurately made was at the Royal Institute of Serology in Copenhagen.

Dr. Jay F. Schamberg of Philadelphia said he had had some 60 Wassermann tests made, most of them being patients in private practice, and the readings had in a large part tallied with the clinical findings, and they had been of inestimable value to him from a diagnostic and therapeutic viewpoint. Salvarsan, particularly when administered intravenously, had a far more efficient effect on the manifestations of syphilis than had mercury, barring exceptional cases, and there were cases, particularly those of the malignant type, that utterly resisted mercury and in which the effects of salvarsan were magical.

Dr. James C. Johnston of New York said there was no doubt about the value of the Weil test in late syphilis. In one case of bilateral hemianopsia due to retinal arteritis the man gave a negative Wassermann and a plus Weil. He received an injection of salvarsan, and his visual fields returned almost to normal within ten days; he was then given a second injection, and his eyesight became practically normal. In syphilis of the nervous system the examinations they had thus far made seemed to show that the Weil test did not act as well as the Wassermann.

Dr. Engman said this entire question hinged largely upon the man who did the work and the reliability of his reagents. He regarded the Wassermann test as a most valuable adjunct in the treatment of syphilis.

Treatment of Malignant Syphilis.—Dr. Howard Morrow of San Francisco said the term malignant syphilis had been loosely applied to various forms of lues which ran a severe course. Some of these cases developed ulcers and rupial lesions in the early stages of the infection, and occasionally such cases ended fatally. In others there were severe constitutional symptoms, and different forms of syphilides appeared, notwithstanding the use of mercury. Another class of cases sometimes spoken of as malignant syphilis was associated with progressive destruction of the nasopharynx, violent headaches, loss in weight, and other severe constitutional symptoms. These were the cases in which treatment with mercury had been unsatisfactory, and a definite prognosis could not be given. Through the courtesy of Dr. Flexner, the writer said he had had opportunity of using salvarsan on a number of patients with malignant syphilis, and judging from the action of the drug in these cases the following conclusions seemed warranted: Salvarsan controlled malignant lues quicker and better than did mercury. Severe infections seemed to clear up as quickly as milder ones. In nasopharyngeal necrosis the action was quick and sure. If given early in lues, either alone or in conjunction with mercury, cases of malignant lues would become clinical rarities.

Dr. John A. Fordyce of New York said he was fully convinced that salvarsan had its most beneficial effects in malignant syphilis where the patients had become immune to mercury or were intolerant to this drug. In addition to its remarkable effects in malignant syphilis, it was most beneficial, in his opinion, in the early stages of the disease. It was his belief that the administration of salvarsan in two or more doses in the early period of syphilis, followed by a mercurial course of several months, offered the patient the best hope for a speedy eradication of the infection.

Dr. William A. Pusey of Chicago said that, like Dr. Morrow, he had seen the most striking effects of salvarsan in healing the serious lesions of syphilis, but it seemed to him that we must recast some of our previous knowledge of syphilis if we were to accept all of the cases of so-called malignant syphilis that were being reported in the articles upon salvarsan. All the works on syphilis, Dr. Pusey said, spoke of malignant syphilis as a very rare condition, and he had come to wonder whether the enormous number of cases which were coming to light in the literature of salvarsan, and which were being reported as unamenable to mercury and potassium iodide and rational treatment, was not a state of mind rather than a fact.

Dr. S. Pollitzer of New York said we heard more about these cases since the introduction of salvarsan because the results of the new therapy were so striking that they were often published.

Dr. E. Wood Ruggles of Rochester, N. Y., said he did not think that laboratory findings always corresponded with clinical results. It had been shown, for example, that argyrol and other germicides had no effect on certain microorganisms, particularly the gonococcus, in the test-tube, yet no one would deny their effect on these organisms in the human body.

Dr. Abner Post of Boston said there was no question about the very valuable effects of salvarsan in malignant syphilis.

Dr. Frederic J. Leviseur of New York reported a case of malignant syphilis which was interesting on account of the difficulties that surrounded the diagnosis, the long course of treatment that the patient had undergone, both in this country and abroad, and the remarkable improvement that followed the use of salvarsan.

Dr. Morrow, in closing the discussion, said that in the cases he reported the patients had received tonic and hygienic treatment in addition to the specific medication. Both patients had been given inunctions and large doses of potassium iodide.

Erythema Nodosum Syphiliticum (Mauriac).—Dr. Frederic J. Leviseur of New York read a paper on this subject, in which he offered the following conclusions: (1) Mauriac's disease was a form of syphilis. (2) The striking resemblance between Mauriac's and Bazin's disease was becoming more and more apparent. (3) It was a malignant form of syphilis (precocious tertiary), frequently preceded, accompanied, or followed by the formation of gummata. (4) It was liable to be mistaken for rheumatism or an accidental combination of both rheumatism and syphilis.

Friday, May 26—Second Day.

A Fatal Case of Blastomycosis.—Dr. Francis J. Shepherd of Montreal reported the case of an Italian, 25 years old, who had lived in Canada two years. Four

months prior to his admission to the Montreal General Hospital he first noticed an ulceration on the side of the nose, which became covered with a crust. When Dr. Shepherd first saw him, in August, 1910, in addition to the eruption on his face, there was a sinus, discharging pus freely, leading down to diseased bone at the sternal end of the right clavicle. Also a fluctuating swelling over the second lumbar vertebra. The growth on the face covered the upper three-fourths of the right side of the nose, extending up to the inner canthus of the eye, and was continuous with a fungating growth below the right lower eyelid. The lesion over the nose was ulcerating and discharging pus. The case proved to be one of blastomycosis, and the organisms were found in the discharges from the sternoclavicular sinus and the dorsal abscess. Subsequently, various sinuses developed in connection with the joints and bones, and the patient died from exhaustion four months after entering the hospital. The autopsy revealed disease of the lungs and the invasion of the organs and tissues with blastomycetes.

Considerations on Lupus Erythematosus.—Dr. A. Ravogli of Cincinnati read this paper.

Three Unusual Forms of Cutaneous Tuberculosis.—Dr. Howard Fox of New York gave a detailed report of these cases.

A Micrococcus with Unusual Characteristics as a Factor in a Resistant Dermatosis Resembling Acne Vulgaris.—Drs. Henry Rockwell Varney and L. T. Clark of Detroit reported in detail five cases in which a micrococcus with unusual characteristics was isolated. Some clinical features were common to all of these cases. They were uniformly of unusually long duration, all existing over eight years, and one twenty-four years. A summary of the findings in these cases indicated the following points: (1) A micrococcus considerably unlike the *Staphylococcus pyogenes albus* might cause lesions in the skin which were acneiform, and which differed in their clinical history and treatment. (2) This micrococcus differed in morphology and in some cultural characteristics from the strains of *Staphylococcus pyogenes albus* they had studied. (3) Antisera produced by the micrococcus agglutinated the cultures of their origin in higher dilutions than did sera from strains of the *Staphylococcus pyogenes albus*. Cross agglutination tests showed the agglutinations of these sera to be specific to cultures of the class of their origin. (4) The acneiform eruptions in which this organism was found persisted long after the acne age, and, while utterly resistant to the usual acne therapy, they had been cured by vaccines made from the organism. The authors stated that, while their experiments in attempting to differentiate between a micrococcus isolated from skin lesions and the easily recognized common organism were not decisive, they were convinced that sufficient differences existed to warrant further study.

Dr. Martin F. Engman said that when one isolated an organism from any skin lesion it was very difficult to say that it was the specific organism pathognomonic of that particular disease. Still, the work of the authors of this paper was very convincing on account of the serological tests that had been employed. There were undoubtedly many acneiform lesions that would have to be taken out of the vulgaris group. The speaker said he believed from his own investigations, as well as those of Dr. Gilchrist and others, that the acne bacillus was really the cause of acne vulgaris, but it was very probable that other forms of acne were due to other specific organisms.

Dr. George T. Jackson of New York said he had seen one of these cases while in Detroit last spring, and it was absolutely unique so far as his experience went.

Toxic Dermatoses: Dermatitis Herpetiformis, Pemphigus, and Some Other Bullous Affections of Uncertain Place.—Dr. M. B. Hartzell of Philadelphia opened a general discussion on this subject. He said that for the sake of convenience of discussion toxic dermatoses might be divided into two groups, the first comprising such affections as erythema multiforme, urticaria, and the eruptions produced by drugs and serums, in which the toxic character of the affections was definitely known and therefore undisputed; the second, comprising such diseases as dermatitis herpetiformis, pemphigus, and certain other bullous diseases of somewhat uncertain place, in which the definite proof of their toxic origin was yet lacking to a considerable degree. The writer then discussed in detail the relationship of the members of the second group to those of the first and to one another, and briefly considered the evidence for their toxic nature. He concluded by expressing the belief that the affections comprising the second group, as well as those belonging to what he had designated as the first group, were toxemias due to a great variety of toxic substances which might be introduced into the body from without, or might arise from autointoxication or from local or general bacterial infection; and that, although they differed from one another sufficiently in their symptomatology and course to entitle them to be considered as separate and distinct affections, they were essentially one in their pathogenesis.

Toxic Dermatoses.—Dr. John A. Fordyce of New York continued the discussion of this subject. He said the view was no longer held by dermatologists that erythema multiforme and urticaria were distinct entities, but that they were skin reactions due to irritants of most diverse origin. While the one was probably always the result of some irritant from within, uticaria might follow both the introduction of or contact with some toxic substance. The etiological factors concerned in urticaria were well known, and it had for a long time been recognized that a special susceptibility on the part of the individual must be invoked, but it was only within the last few years that an attempt had been made to explain this so-called idiosyncrasy. It was Wolff-Eisner who first claimed for urticaria a uniform etiology, namely, an anaphylaxis against alien proteid. Anaphylaxis had been familiar to the medical world for years, and many attempts had been made to study its mechanism, but it was not until 1902 that anaphylaxis and immunity were first differentiated. This was done by Richet in his classical experiments with actinia extracts, by which he demonstrated that an animal could be so sensitized to an injection of a nontoxic dose that a second injection of a minimal quantity, after a certain interval, proved fatal. The following year, Arthus, using horse serum, obtained similar phenomena. About the same time, von Pirquet and Schick, working along similar lines, first definitely classified the symptom-complex, which developed after the injection of therapeutic sera as serum disease. This they interpreted as a reaction to a specific foreign proteid The process of anaphylaxis consisted of the introduction of a foreign proteid to which the organism responded by producing an increase of antibodies for this substance. On the administration of a second dose, after the so-called incubation period, of even a minute quantity, the proteid was so rapidly disintegrated by the antibodies that toxic products were set free and then gave rise to the clinical phenomena. The further disintegration of these toxic products rendered them harmless, and the attack subsided. The familial susceptibility which was sometimes met with in addition to individual idiosyncrasy was not sufficiently explained, according to some authors, by the anaphylactic theory, and they would seek the cause of these phenomena in an inherited instability of the vasomotor system. Dr. Fordyce then discussed the various views regarding urticaria, and said the controversy to-day hinged on the theory of an angioneurotic or inflammatory origin. Reidl and Kraus, from their experiments, concluded that the

anaphylactic state was characterized by a fall in blood pressure and a vasodilatation of the peripheral vessels. Recently Hoffmann had called attention to the relation of internal secretion with the anaphylactic condition and emphasized the fact that urticaria was frequently associated with hay fever and asthma, and that all the conditions were commonly found in hyperthyroidism. He reasoned from this that the glands of internal secretion so influenced the vessel tone by their products that they were an important factor in the production of anaphylaxis. In conclusion, the author stated that, although the many and varied conditions under which the erythema group of skin diseases occurred pointed to a plurality of causative agents, we had no more plausible explanation of their *modus operandi* than that advanced by the theory of anaphylaxis. It elucidated the vague terms idiosyncrasy.

Some Toxic Effects in the Skin of Disorders of Digestion and Metabolism.—Dr. James C. Johnston of New York discussed this phase of the subject. He said there appeared no weighty reason for dividing the toxic disorders of the skin into classes, especially if the classification showed a tendency to rigidity and so limited a proper view of causative factors in any given instance. The difficulty of division lay in the overlapping of these factors. However, if this objection be kept in mind, a separation into three groups was permissible: first, disorders due to derangement of digestion; second, of intermediary metabolism; third, those due to anaphylaxis. For example, although urticaria was at present the only autotoxic eruption which had been experimentally demonstrated to be an anaphylactic phenomenon, it was rare to find a chronic case uncomplicated by gastric symptoms. Prurigo's relationship to urticaria was close, but it was associated with evidence of disturbance in intermediary metabolism, and if anaphylactic shock was a factor it must be only partial. Conversely, anaphylaxis in the human being commonly expended its force not on the respiratory apparatus, but on the gastrointestinal tract, as was amply proven by cases of serum disease. After all, it mattered very little whether indigestion was primary or secondary; it claimed attention in either event. Dr. Johnston then discussed in detail these three groups of toxic disorders, and reported illustrative cases.

The Toxic Origin of Erythema Multiforme.—Dr. Henry G. Anthony of Chicago said that erythema multiforme was a toxic dermatosis produced by many toxemias. It was closely allied to and often associated with urticaria, and also with purpura. In the presence of a case of erythema multiforme with urticaria one suspected that the toxemia was derived from the gastrointestinal tract, while when the association was with purpura the toxemia was more apt to be derived from some focus of infection, or from ptomaine poisoning. Erythema nodosum was one of the many manifestations of erythema multiforme rather than an independent affection, as was formerly supposed. A toxemia from pharyngitis or from an infectious disease such as malaria might assume the form of erythema nodosum in one case and any other form of the eruption in other cases. Clinical observations led one to believe that the form which the eruption took depended on the dose and virulence of the toxins absorbed, on the vitality of the individual, and on the functional integrity of the eliminating organs. In the terminal stage of nephritis, especially in the aged, the tissues frequently exhibited a diminished vitality, as was shown by the lesions which resulted from trivial traumatisms. Erythema multiforme occurring in such individuals usually assumed the bullous type. In discussing the treatment of erythema multiforme, the speaker said that in this condition elimination was frequently interfered with by the presence of toxins in the system, and such patients were salivated by doses of mercury which they could easily tolerate in health, administered under the mistaken diagnosis of syphilis. He had observed more cases of mercurial stomatitis from moderate doses of mercury in erythema multiforme than in any other dermatosis. The salicylates were toxin eliminators, and possessed the power of destroying microorganisms in the system. They were more powerful eliminators of certain toxins than of others: hence, they exerted a greater curative influence on some cases of erythema multiforme than on other cases, while in some toxemias they were entirely impotent. Still, they were the most powerful toxin eliminators which one possessed, and where continued for some time they were of value even in severe cases of thrombophlebitis.

Dr. A. Ravogli of Cincinnati said he agreed with Dr. Hartzell that dermatitis herpetiformis was nothing but the result of a toxic condition. The speaker said he regarded pellagra as a toxic erythema produced either by the absorption of mouldy substances found in decayed corn or from the presence of fermentative elements remaining in the intestines.

Dr. Schamberg said that some very interesting facts were to be gleaned from a study of the serum eruptions. The periods of incubation of serum phenomena from the sera of different horses varied considerably, from two to fifteen days or longer. Likewise, different horse sera varied greatly in their tendency to produce rashes. He had seen diphtheria serum uniformly produce an eruption in eight or nine days, whereas the serum from another animal would produce an eruption in two or three days.

Dr. Joseph Grindon of St. Louis said that eosinophilia in dermatitis herpetiformis, to which Dr. Hartzell referred, was of little value in establishing the differential diagnosis between that disease and pemphigus.

Dr. William T. Corlett of Cleveland, referring to Dr. Johnston's statement concerning hyperacidity associated with rosacea, said he thought it was well established that such was the case. For many years he had observed that an erythema surrounding the mouth was almost invariably associated with gastric disturbance.

Dr. Engman said there were a certain group of eruptions which were undoubtedly the result of intestinal toxemia. In certain individuals such a toxemia would produce a pompholyx, in others a multiple erythema, and in others a pemphigus. By putting our pompholyx patients on a vegetable diet, it was remarkable to see how rapid their recovery often was. In these cases the vegetable diet must be absolute.

Dr. Pusey said we were now groping in the dark, looking for tangible facts about the action of toxins in the body, and he called attention to the recent monograph by Martin Fisher, a prize essay of the Philadelphia College of Physicians, upon the affinity of colloids for water of different degrees of acidity. This, perhaps, pointed to a working theory for many of the phenomena that occurred in the toxic erythemata.

Dr. Hartzell, in closing, said there were certain toxic dermatoses, the so-called septic dermatoses following septic wounds, in which the symptoms were due to the absorption of bacillary toxins from localized foci of infection, as distinguished from a general infection.

Dr. Fordyce, in closing, said the discussion had emphasized very distinctly that the toxic dermatoses were not due to any one cause, but were skin reactions due to a variety of causes.

Dr. Johnston, in closing, said that while we heard a good deal of the multiplicity of these eruptions and their causes it was no less a fact that the same cause might produce multiple effects: for instance, from the same cause we might have a pemphigus, a pompholyx, or a purpura; the cutaneous type, however, generally ran true in the individual.

Xanthoma Tuberosum Multiplex.—Drs. S. Pollitzer

and Udo J. Wile of New York presented what was largely a pathological report, based upon the study of a number of sections from several cases of xanthomata observed during the past twenty years, and of material obtained by biopsy of a case recently under the authors' observation.

Saturday, May 27—Third Day.

A Case of Acanthosis Nigricans.—Dr. Charles J. White of Boston reported this case in detail, with histological findings.

Multiple Areas of Pigmentation of Eight Years' Duration Involving Chiefly the Trunk of a Girl of Twelve: Histological Examination and Review of the Literature. Dr Frank Crozer Knowles of Philadelphia read this paper.

Report of Eosinophilia in Scabies, with a Discussion of Eosinophilia in Various Diseases of the Skin.—Drs. Jay Frank Schamberg and Albert Strickler of Philadelphia read this paper.

Veronal Poisoning.—Dr. S. Pollitzer of New York said that since the introduction of veronal as a hypnotic about eight years ago a considerable number of cases of poisoning with the drug had been reported. The medicinal dose of veronal was from one-half to one gram, but the range of toleration was a rather wide one; single doses up to eight or ten grams or more had been taken without harmful effect. Umber reported the case of a healthy woman who recovered after a single dose of twenty grams. Among the symptoms recorded in cases of toxic effects from medicinal doses of the drug, vertigo, nausea and vomiting, stupor or mental confusion, muscular weakness, thirst, and a macular and vesicular eruption on the skin, resembling an antipyrin rash, were mentioned. The symptoms varied considerably, however, in different cases, and in general one might divide all these cases into three groups: those in which a single large dose was taken by accident or with suicidal intent; those in which patients had exhibited an idosyncrasy to even small doses, and those in which the continuous use of the drug in medicinal doses over a long period had resulted in the sudden development of toxic symptoms. Dr. Pollitzer then illustrated these types with a few cases from the literature, and reported in detail one case of the cumulative type that had come under his observation. In concluding his paper, he emphasized the importance of care in the administration of this valuable hypnotic. It should, of course, never be given undissolved, and it should not be administered daily over long periods of time, lest it exercise harmful cumulative effects.

AMERICAN ELECTROTHERAPEUTIC ASSOCIATION.

Twenty-first Annual Convention, held at Philadelphia, September 5, 6, and 7, 1911.

The President, Dr. Frederic de Kraft of New York, in the Chair.

Addresses of welcome were delivered by Mr. Gleason, Secretary to the Mayor of Philadelphia, and by Dr. C. B. Longenecker, President of the Philadelphia County Medical Society. Dr. Charles R. Dickson of Toronto responded on behalf of the Association.

Presidential Address: The Development of High Potential Currents as Applied to Medical Uses.—Dr. de Kraft traced the development of this mode of treatment from ancient times down to the present.

Report on Direct Continuous Current.—Dr G. B. Massey of Philadelphia read this report. The committee felt that too little attention was still bestowed in this country on medicamental ionization with low volt currents. It was possible that one failed to obtain the full results on account of defective technique. Too little skin surface was used for the diffusion of the ions through the skin. With the parts immersed in local baths, the electrodes would not irritate the skin unduly. Instead of the baths, one might employ very large electrodes of several layers of absorbent cotton wetted with the solution, over which a bandage-like strip of tinfoil might be wound, to which a thin wire was attached by simply threading it to a corner and bending the corner on itself.

Report on Induced Currents, Including Alternating and High Frequency Currents and Apparatus.—Dr. Frederick M. Law of New York made this report. In using the D'Arsonval current the amount of dielectric had a marked influence on the therapeutic effect, the greater the amount of the dielectric the more superficial the effect and the more influence felt on the sensory nerve endings. Eddy currents were generated within the body which acted as a gentle massage. A valuable use of this current was in intestinal autointoxication. The use of the bipolar D'Arsonval current might be fraught with danger unless carefully performed. Dosage should be governed by the effect on the patient. The construction of the resonator had a great bearing on the effect of the discharge. Very little could be done with a small resonator.

A Note on the Electrical Treatment of Obesity.—Dr. F. Howard Humphris of London, England, described the method of Prof. Bergonié of employing electricity in the treatment of obesity in order to provoke a general exercise or stimulation of the muscles of the body. This method consisted in causing the contraction of the muscles some one hundred times a minute by means of a current derived from what might be termed an induction coil, or a coarse wire faradic, whose coefficient of transformation was 2 or 3, the current being interrupted by means of a metronome. Rheostats were used so that each part of the body received that amount of electricity which it could comfortably bear. The electrodes covered as large a surface of the body as possible.

Report on Static Currents and Apparatus.—Dr. Herbert F. Pitcher of Haverhill, Mass., made a plea for the continuance of the use of static electricity. The men who claimed that with the advent of the high frequency apparatus the era of the static machine was passing were either warped in their judgment or were ignorant of the currents and therapeutic effect of the static machine. No high potential apparatus had yet been produced which would induce the physical effects of the tissue pulsation with resulting tissue drainage.

On the Use of Compressed Gases for Increasing the Efficiency of the Static Machine.—Dr. F. Howard Humphris of London, England, read this paper. Anything which would enable the physician to charge his static machine rapidly and in all weathers, and also to increase its capacity of voltage, must be welcome. Some time ago he conceived the idea of leading into the case some fresh air passed through sulphuric acid and ice, and removed by means of a suction pump at the other side of the case. But the simpler procedure of replacing the moist impure air by CO_2 or liquid air he decided upon trying first. On the subject of liquid air a report would be made later. The experiments with CO_2 had been so successful that, given a static machine in good running order and a cylinder of CO_2, it could be made to charge in all weathers and in all climates, and, moreover, in a given machine from which the current was insufficient with CO_2 the capacity and voltage could be readily increased from 20 to 30 per cent.

Report on Phototherapy.—Dr. Edward C. Titus of New York said that the committee had endeavored to determine whether the beneficial action of phototherapy was due to heat or to light, or both together. Considering the very powerful effect of certain invisible, noncaloric luminous radiations, the analgesic and soothing action of certain kinds of light, it must be admitted that their effect could not be attributed to heat, or only in a minor degree. The

luminous radiation was the principal, if not the unique, element of this action. The committee recommended plans for the construction of a modern electric light bath cabinet.

Report on Röntgenology.—Dr. G. E. Pfahler of Philadelphia reviewed in detail the recent advances in rontgenography and röntgenotherapy, dwelling particularly upon the use of the *x*-ray in the diagnosis of abdominal conditions.

Report on Standardization of Physical Therapeutic Measures.—Dr. William Benham Snow of New York read this report. The wisdom of the establishment of standards for the employment of electrotherapeutic and other physical measures was demonstrated as year after year the papers read before the Association partook less of the empiric. Rational medicine demanded rational standards and the universal recognition of the laws of physics and the action of physical agents upon the human organism in conformity with the various demonstrable physiologic effects and their action upon pathological conditions.

Some of the Therapeutic Indications of High Frequency Currents.—Dr. Herbert F. Pitcher of Haverhill, Mass., outlined some of the more common conditions and diseases in which the high frequency currents were indicated.

Static Electricity in Nervous and Mental Diseases.—Dr. J. J. Kindred of Astoria, L. I., dwelt particularly upon the use of electricity in the relief of pain, nervous instability and brain fatigue, anterior poliomyelitis, tabes dorsalis, dementia precox, hypertension and arteriosclerosis, and neurasthenia.

The Rational Treatment of Cardiovascular Disease.—Dr. William Benham Snow of New York said the rational treatment of cardiovascular disease consisted in the removal of the cause and the relief of existing conditions. If due to toxemia, the latter should be limited by evacuation with cathartics and high colonic flushings, the administration of intestinal antiseptics, and the limitation and selection of proper foods. Rowing teams in colleges should be abolished. College youths who had developed cardiac hypertrophy should be warned against lapsing into a quiet life. In tachycardia due to hypersecretion of the thyroid, treatment of the gland by the *x*-ray promptly relieved the tachycardia and dyspnea in these cases. The autocondensation method of treatment of hypertension was one of the most valuable additions to the materia medica, and might be used in all cases except where parenchymatous nephritis was present. This method had been used with uniform success, employing the couch, with a current of four or five milliampères for twelve minutes daily or upon alternate days, or less frequently, according to indications.

Benefits from the Employment of Electricity in Gastrotherapeutics — Confirmed Results and Deductions from Over a Thousand Cases.—Dr. Anthony Bassler of New York. The cases studied were uncomplicated primary cases of sensory, secretory, and motor disturbances. In the hyperesthesia cases continuous galvanism with the positive pole internally was useful. In obscure enteralgias and tenderness along the colon galvanism was worthy of trial. In neurasthenias the speaker's experience had been that the high frequency and static currents were best. In the secretory cases, if no motor disturbances were present, the galvanic current was used. The best results of treatment were obtained in the myasthenic and the atonic cases.

Elimination.—Dr. Charles O. Files of Portland, Me., said that elimination had always been considered of great importance in the treatment of disease. The old methods of bloodletting, large doses of calomel and jalap, or small doses of calomel for the purpose of inducing salivation, the use of tartar emetic, cupping, blisters, setons, and moxas had happily passed away. The necessity of getting the emunctories to work, of stimulating all the excretory organs, would never go out of fashion. One has in physical therapeutics the means of accomplishing the desired end without doing violence to other organs. These means were hydrotherapy, radiant light and heat, massage, electricity in many modalities, and vibration.

The Treatment of Constipation.—Dr. H. M. Imboden of Clifton Springs, N. Y., said that dyschezia would usually be corrected by the establishment of regular habits. Hot and cold douches to the perineum were good in some cases. The static wave current with the electrode introduced into the rectum had been very satisfactory, the treatment being given just before the hour selected for defecation. Glycerine suppositories might be used in some cases. Enemas must be used occasionally. In the class of cases in which the feces passed slowly through the colon the measures to be used were diet, exercise, the interrupted continuous current, cold sitz baths, the alternating pan douche, and deep abdominal kneading, with the hand or the vibrator.

Enforced Compensation.—Dr. Gustavus Werber of Washington, D. C., did not consider compensation in its usual application to designate the readjustment of the histological elements of various organs to bridge over the danger caused by morbid processes, but only in its broadest sense to include all those processes by means of which nature protected herself against the results of disease or accident. The paper was offered as a speculation as to the means of increasing control of these forces. Among the means that had been used to this end were faith, fasting, heat, cold, drugs, sudden loss of blood, hypnotism with suggestion, physical exercise, by challenge or placing the *vis* on the defensive, and by anything which depressed the index of vital resistance and is followed by reaction.

Acute Bronchopneumonia (?) Relieved by the Static Wave Current—Report of a Case.—Dr. A. B. Hirsh of Philadelphia reported a case of acute pulmonary infection in which, after other measures had failed to give relief, a metal electrode 4 by 8 inches placed over the front of the upper chest and a twelve-minute application of the static wave current was given. Its effects were so prompt in relieving the pressure and weight within the chest, the cough and bloody sputum, that the current was used morning and evening for several days, and the patient went on to rapid recovery.

A Rational Muffler for the Static or High Frequency Spark.—Dr. George E. Pfahler of Philadelphia presented a muffler that he had devised. It consisted of two glass plates (cleaned *x*-ray negatives, 14 by 17 inches were used), which formed the top and bottom of the box constituting the muffler. The sides of the box, made of hard rubber, were 5 inches deep and closely fitted the outside of the glass plates. Holes were cut in the ends for the passage of the sparking rods.

The Rational Treatment of Duodenal Infection.—Dr. Frederick H. Morse of Boston, Mass., read this paper. Duodenal infection might be acute and of little consequence. Rigid diet and a little antiseptic medication would bring about a cure. In the chronic conditions of duodenal toxemia where the infection had gone through the meshes of the diseased bowel the infiltration of the poison was so far outside of the immediate digestive tract that the usual medicinal efforts availed nothing. This was where vibratory impulses set up by electricity and other physical methods were the most effectual means of eliminating the infection. The modalities mentioned in the treatment were the sinusoidal, faradic and galvanic surging apparatus, and the wave current from the static machine. A long train of symptoms ordinarily called rheumatism, rheumatic sore throat, sciatica, constipation, neuralgia, etc., were usually cured when the pent-up toxemic infection was removed.

Is the Present Attitude of the Medical Profession Toward Physical Therapeutics Justifiable?—Dr. J. C. Walton of Richmond, Va., said that while it was frankly admitted that physical therapy had its limitations, and it was not claimed by its most enthusiastic devotees to be a panacea, still it filled a very important place in therapeutics, and there should not be any antagonism between this and any other progressive rational system of therapeutics, especially drug and serum therapy, and that very important branch of therapy, the therapy of the ductless glands. The sole object and aim of the true physician was to cure his patients, and to accept the truth wherever found. He should always approach the solution of these great problems in therapeutics with an open and unbiased mind, striving diligently to ascertain the truth.

Three Cases of Pellagra Treated by High Potential Currents.—Dr. D. H. Yates of Madison, Fla., presented this paper, which was read by the secretary. The author was led to use this treatment from the similarity of the skin lesions to those of chronic eczema. The method was applied as follows: The patient was seated on an insulated platform with the shoes removed. The feet were placed on the metal plate, and the plate connected to the positive side of the static machine. A crown electrode was connected to the stand support above the patient's head and connected by a wire or chain to the negative side of the machine. The machine was started with the spark gap closed, and the sliding rod was then drawn out as far as possible without causing painful contraction of the muscles of the leg. The machine was regulated so as to give about 200 discharges at the spark gap per minute. The author thought that the efficiency of this current in these cases, as in other cases, was due to its influence on metabolism.

Arsenionization in Inoperable Cancer—A Preliminary Note.—Dr. G. Betton Massey of Philadelphia said that the possibility that the ions of arsenic when electrically diffused might be more efficacious as a local surgical protozoacide than the zinc-mercury ions suggested itself to the author shortly after the announcement of salvarsan. The experiments to test the question were begun in October, 1910. All but one of the patients on whom the treatment had been used were still under treatment, and it was too early to state the results of these experiments. The pure arsenic ion was obtainable from metallic arsenic shaped into an electrode so that it might be applied as the anode of a direct current when thrust into the middle of the growth, the cathode being placed elsewhere on the body surface so as to secure a good contact with the least local action under this pole. The result of this treatment was the production of a dark slough. Each patient subjected to the treatment had improved in general health more rapidly than under the zinc-mercury ions.

Neurasthenia and Its Treatment by Electricity.—Dr. F. Howard Humphris of London, England, said that rest was applicable only to the milder forms of neurasthenia. The patient should not have too much to do with his relatives. The treatment most successful in the speaker's hands was that by one or other of the various forms of electricity. The form of electricity must vary with each class of case. Where the blood-pressure was subnormal the application of the static brush discharge to the bare spine was the most successful. During treatment the patient was encouraged to go on with his work, keeping regular hours and avoiding alcohol and fatigue. In cases in which the arterial tension was high the direct D'Arsonval current was employed. For insomnia the hot mustard foot bath was to be used. Where the appetite was poor bitter tonics were to be administered.

Thermotherapy.—Dr. Byron S. Price of New York said that body thermotherapy of 350° F. and upward was especially indicated as a general and rapid eliminant in septic and toxic conditions, and was of great importance as an addition to the action of currents. It reflexly produced profound tonic metabolism and elimination (through the nervous system and increased activity of circulation), measured by uranalyses, decrease in hypertension and later improved health. All depression to nervous and circulatory system appeared to be completely prevented by short high temperature treatments, and by maintaining the peripheral and glandular circulation. This was accomplished by inaction on the part of the patient, and immediate transfer to the hot water bath, followed by salt rub and suitable friction massage and upward of five hours' absolute rest.

Treatment of Poliomyelitis Anterior.—Dr. Grafton E. Day of Collingswood, N. J., said that the prophylaxis of this disease consisted in quarantine, disinfection of the secretions, and the giving of urotropin to those exposed. Urotropin administered in the beginning of an attack would prevent paralysis in the majority of cases. Curative measures were the following: Prompt and thorough elimination with calomel, castor oil, or an enema; the ice cap; easily digested foods; diuretics; hot pack to increase diaphoresis; the administration of urotropin from the beginning; lumbar puncture to relieve intense pain; sedatives where other measures failed to relieve suffering; affected member was to be wrapped in cottonwool; threatened deformity should be set by the use of properly fitting braces; massage and active and passive movements were most valuable. Galvanic stimulation should not be delayed beyond three weeks. Radiant light and heat were also good.

Report of a Case of Pyelonephritis Treated by the Static Wave Current, with Exhibit of Case.—Dr. S. Leslie West of Philadelphia exhibited a case, a girl 15 years of age, who presented the usual symptoms of parenchymatous nephritis complicated by a suppurative pyelitis. The Morton wave current was given over the region of the kidney and liver, followed by the brush discharge over the whole length of the spine. Improvement began from the start. Treatment was continued for twenty-five days. The patient had been well since the first of this year.

Subacromial or Subdeltoid Bursitis Often Mistaken for Brachial Neuritis.—Dr. Park S. Breneman of Lancaster, Pa., stated that since beginning his investigation of this condition he had examined twenty-five or thirty cases with pain in the arm more or less marked that might lead one to believe that bursitis was present. In eight of these cases a shadow of the bursa or contents of the bursa was distinctly shown. In one, a traumatic case, a shadow was shown which the speaker took to be a fracture of the tuberosity of the humerus with uplifting of the fragment, which might easily be mistaken for a bursa. In nine cases a more or less distinct shadow in the position of the bursa was shown. In the balance of the plates the condition of the shoulder appeared normal. All cases should be examined with the *x*-ray before treatment. In the acute condition where the shadow was not found the arm should be put at rest and palliative measures used. Where the shadow showed the remains of a bursitis the adhesions should be broken up under an anesthetic. Electricity and massage played an important part in the treatment.

The Question of Scarlatinal Immunity.—Von Szontagh agrees with Czerny that a scarlatinal immunity does not exist; that one attack does not protect one from subsequent attacks; that an individual may be exposed to cases of scarlet fever and not take the disease, while later, without exposure, he may acquire the infection. The poison of scarlet fever is ubiquitous and resides in and about the individual. Scarlet fever is naught else than a sepsis (toxemia) or pyemia (bacteriemia) of cryptogenic origin, or a combination of both.—*Jahrbuch für Kinderheilkunde.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ended September 23, 1911:

	Cases	Deaths
Tuberculosis Pulmonalis	465	155
Diphtheria	192	11
Measles	86	3
Scarlet Fever	56	2
Smallpox	—	—
Varicella	23	—
Typhoid Fever	154	22
Whooping Cough	47	11
Cerebrospinal Meningitis	4	5
Malarial Fever	—	
Totals	1,027	209

Observations on Scarlet Fever.—Gigon of Basle, in reporting his study of 483 cases of scarlet fever, notes that, occurring as sequelæ, pertussis, measles and diphtheria do not run any abnormal course. On the other hand, varicella is a severe complication. Scarlatinal rheumatism was manifested only in adults. Adenitis, nephritis and cardiac lesions appeared chiefly in the third week, while otitis and arthritis appeared principally in the first and second weeks. Scarlet fever was particularly common after burns.—*Jahrbuch für Kinderheilkunde.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended September 22, 1911:

Places	Date	Cases	Deaths
CHOLERA			
Austria-Hungary: Arbe	Aug. 21–27	2	2
Cittanuova	Aug. 21–27	1	1

BACILLUS COLI INFECTION OF THE URINARY TRACT.

BY REGINALD M. RAWLS, M.D.,

NEW YORK.

ASSISTANT SURGEON WOMAN'S HOSPITAL; GYNECOLOGIST TO NORTHWESTERN DISPENSARY, PHYSICIAN TO DEMILT DISPENSARY.

DURING the past twenty-five years original workers have given much thought and study to the *Bacillus coli communis*. Early it was found present in the intestinal tract of man and the higher animals. When found in other organs, at autopsy, it was considered of no importance, as it was believed to be due to a post-mortem change. From some recent work of Conradi,[1] this may be but an exaggerated normal condition. He has shown that in health a few microrganisms, especially the *Bacillus coli* and *Streptococcus fecalis,* in small numbers are continually invading the solid organs, as well as the mucous tracts, and that they are as constantly being killed. Laruelle and Tavel, in 1889, first made known the pathogenic properties of the *Bacillus coli* and the latter first found it, in life, outside of the intestinal tract. Roswell Park[2] in 1893, in a paper entitled "The Importance to the Surgeon of Familiarity with Bacillus Coli Communis," reviews the literature and gives Welch and Councilman credit for the name "colon infection," and to Clado and Albarran priority for classifying the *Bacillus coli* as a urinary pyogenic organism.

In the early literature Roberts[3] (1881) first described bacteriuria, and as late as 1903 Blumenthol, quoted by Shaw,[4] pointed out that "bacteriuria occurs in cystitis and pyelonephritis, producing a diffuse but uniform turbidity of the urine," but he does not give special attention to the microorganisms causing this change. R. Barlow (1897) and Victor Blum (1904), quoting Shaw, give an excellent summary of the various clinical types of colon bacilluria. In 1895 Brown[5] reported a case of cystitis, pyelonephritis, and pyonephrosis due to the *Bacillus coli*, with illustrations of two kidneys in different stages of infection. In 1902 Burch[6] reported that for ten years he had observed a series of cases which ran a typical typhoid course for a week or ten days, but with a daily negative Widal, although the diazo reaction was always well marked. The urine was always acid and in many cases contained traces of albumin and sometimes a few granular casts. It was often turbid and swarmed with peculiar motile organisms resembling the typhoid bacillus, which on culture responded to all tests for the colon bacillus. He considered these as cases of colon infection pursuing the course of typhoid. From our present knowledge it seems we would be justified in classing these cases as colon bacillus infections of the urinary tract. In 1889 Kruse,[7] and in 1892 Reblaud,[8] first called attention to pyelitis of pregnancy, and in 1905 Smith[9] reviewed the literature and collected fifteen cases. In thirteen of these a bacteriological examination had been made, and all but one showed a pure culture of *Bacillus coli*. In 1905 Barnard[10] published an article entitled "Multiple Abscesses of the Kidney Due to Acute Ascending Infection of Normal Urinary Tract by Bacillus Coli Communis." In this article he collected all the cases reported from 1895 to 1905, six in number. In but two had a bacteriological examination been made, Wilms and Lennander's cases (1901), and both showed the presence of *Bacillus coli*. Blake's (1902) and Brewer's (1904) cases are among the remaining four in which no bacteriological examination was made. Barnard says that apparently the colon bacillus was responsible for these six cases. In 1906 Brewer[11] reported a series of thirteen cases of unilateral septic infarcts of the kidney, eleven occurring in women, and in eleven the right kidney was the seat of infection. From a bacteriological standpoint two showed colon bacillus, two streptococcus, one staphyloccus, and one showed no organisms after three days. In the remaining seven no mention is made of any bacteriological examination.

Among the early articles on cystitis are the observations of Melchior[12] (1895), in which he reports thirty-five cases with the colon bacillus present twenty-four times, and seventeen times in pure culture. Since his report it has been shown that we may have a bacilluria with a colon infection of the upper urinary tract and yet the mucous membrane of the bladder remains normal. Rovsing[13] (1909) thinks that a cystitis is the rarest manifestation of the colon bacillus, as this microorganism does not possess the power of attacking the intact mucous membrane of the bladder. Among the recent articles is one by Thomson,[14] entitled "Acute, Subacute, and Chronic Infection of the Kidneys and of Other Organs by the Bacillus Coli." He reports a number of cases and refers to most of the literature up to October, 1909. Since that time a number of articles have been published which substantiate the earlier reports and findings.

In the literature the presence of the colon bacillus in infections of the urinary tract is variously estimated at from 42 to 80 per cent. Billings[15] holds that "colon bacilluria occurs in 50 per cent. of cases of bacteriuria." On the other hand, it has been demonstrated that the *Bacillus coli* is present in a certain percentage of cases with normal urine. Murray, Williams, and Wallace[16] found the colon bacillus present in 44.5 per cent. of gynecological cases, with normal urine, examined before operation, and in 93 per cent. after operation. From these observations they conclude that simply finding the colon bacillus present in a catheterized specimen of urine, even with evidences of inflammatory changes, is not sufficient for a diagnosis of colon

bacillus infection, and that these findings should be substantiated by the agglutination test and the opsonic index, and if these are of no value, as thought by Dudgeon, then we are dependent on an improvement from the use of autogenous vaccines to prove our claim of colon bacillus infection of the urinary tract.

The mode of entrance of the bacillus to the urinary tract is in dispute. There are three possible modes of infection, namely, ascending, descending, and transparietal. Each has its advocates, and some accept all as necessary to account for the cases observed.

Ascending Infection.—By this method the bacillus enters the urinary tract by way of the urethra. This theory is favored by Barnard, Box, Bond, Parkinson, Sundberg, Stewart, and Herringham. They base their belief on the fact that the greatest number of cases occur in the female, in infancy and later life, and think this is due to the anatomical condition of short urethra and near proximity of the vulva and anus as contaminating agents. Also, in infancy there is the possibility of the thread worm carrying the infection directly from the rectum to the urethra and bladder. In the male this mode of infection is not so readily explained, although Melchior, quoted by Shaw, has found the colon bacillus in urinary meatus in 50 per cent. of males examined. Others have demonstrated that the foreskin often harbors the bacillus and there is always the possibility of instrumentation carrying the infection. Bond[17] has demonstrated, on postoperative cases, that there is an ascending current from the urethra to the bladder and from the bladder to the kidney, and suggests that this may be present in health. He found that this upward current was more marked when there was an obstruction to the outflow. As further proof of the theory of ascending infection is the frequent kidney infection following transplanting of the ureter into the intestine. Stewart[18] in some recent work has shown that the lumen of the ureter is less a factor in ascending infection than previously supposed, and has demonstrated that infection of the kidney can take place through the lymphatics and blood vessels of the ureter. This causes a perinephritis primary to kidney infection. The examination of some of the kidneys affected by multiple colon abscesses tends to substantiate the theory of ascending infection. Quoting from Barnard, "When the wedge is produced by an ascending infection it is intralobular and the apex passes down into the pyramid." "When embolus is the cause of the wedge, however, the area is interlobular and the apex terminates in the intermediate zone and between two pyramids." As early as 1899 Sunberg recognized this distinction and in his description of Lennander's case (1901) pointed out that wedge shaped abscesses ended in pyramids and were intralobular.

Descending infection, or infection through the blood stream, is advocated by Rovsing, French, Wilson, Dick, Brewer, Posne, and Lewin, Casper, and Kraus. Posne and Lewin, cited by McCrea,[19] injected animals with the bacillus and mechanically occluded the urethra and anus, and obtained a general infection, and the organisms were found in the urine. To exclude direct infection from the intestines, one renal artery was tied and the corresponding kidney did not show infection. Thus they proved the possibility of hematogenous infection. Rovsing thinks most cases are caused by the organisms being deposited, by the blood, in the kidneys, thus causing a diffuse nephritis which is most often slight, but occasionally acute. He says the infection may take place by way of the urethra when there is a paralysis of the sphincter, or by instrumentation, and occasionally it may spread from neighboring organs. Since 1897 he has treated 285 cases of *Bacillus coli* infections, and in 180 of this number the disease arose as an acute nephritis, and in no instance had the patient been catheterized. Some of the starting points in this series of cases were tonsillitis, cholecystitis, acute enteritis, colitis, cancer of the colon, and typhoid. French, cited by Wright,[20] strongly favors hematogenous infection in pyelonephritis of pregnancy, and considers that constipation, which is so often present in pregnancy, is a predisposing factor for the bacilli to pass from the intestines into the blood stream. He holds that it strongly argues against ascending infection, as we find, in these cases, the obstruction above the pelvic brim, the ureteric orifices not interefred with, and on cystoscopic examination there is no involvement of the bladder. Quoting Casper,[21] "The numerous cases of infection with the *Bacillus coli communis* which have been observed must be considered as hematogenous; for some unknown reason the system becomes flooded with these organisms and they are occasionally deposited in the kidney or its pelvis." It seems to me that the most conclusive proof of hematogenous infection is found when we have a colon bacillus bronchopneumonia with a bacteriuria and no urinary symptoms. The possibility of colon bacillus infection of the respiratory organs was first suggested by Welch, and recently demonstrated by Von Schrotter and Weinberger.[22]

Transparietal Infection, or Infection by Contiguity.—Early Reymond[23] proved by animal experiments that microorganisms could pass from infected neighboring organs directly into the bladder, and the blood and kidneys remain sterile. Recently Franke[24] has shown that bacteria are able to pass from the intestines into the lymphatic spaces, even if there is only a slight lesion of the intestinal wall. He has demonstrated, by experiments on rabbits, that there is a lymphatic connection between the cecum, ascending colon, and the right kidney, but has not proved a similar connection for the left kidney. Another and more direct method of infection is the rupture of a colon bacillus abscess into the bladder or some other part of the urinary tract. *Bacillus coli* infections of the urinary tract, according to Pardoe,[25] may be either autogenous; "infections not dependent upon any gross disease of the urinary passages, nor accompanied by conditions interfering with the freedom of micturition"; or they may be secondary to such predisposing factors as enlarged prostate, stricture, calculus, some lesion of the central nervous system, or to gonorrhea. These infections are either acute or chronic and their diagnosis is often difficult. In acute conditions the symptoms are those of other acute infections and have been mistaken for influenza, appendicitis, malaria, nephritis, tuberculosis, typhoid, and uremia. At other times the symptoms are so mild they may be overlooked. The chronic cases are most often mistaken for chronic nephritis. Thus we see the necessity of basing our diagnosis on a careful urinary examination plus a definite line of symptoms and clinical findings which I shall now consider.

In the following I offer nothing original, and

take this means of giving full credit to current literature. The cases reported, however, I have observed and offer them as true examples of *Bacillus coli* infection of the urinary tract.

Pollock[26] thinks there are prodromal symptoms of general malaise, slight pain in the kidney and perineum, a dull pain over the bladder with frequent and painful urination, an evening chilly sensation, and rise of temperature. These symptoms may be overlooked and if untreated are usually followed in a week or ten days by more acute symptoms, which may be most severe in character. Often the first symptoms are those of a typical malarial seizure. Herringham[27] found these rigors are but incidents in a continued fever and the pyrexia may fall by lysis, by crisis, or may be hectic; diversified by rigors which may be of almost daily, occurrence; or the temperature may be remittent in type. During the high temperature there is a feeling of general discomfort and aching, and at times there is more or less delirium and restlessness. The pulse is usually not high considering the pyrexia. During an acute seizure it may reach 120, but usually is 100 to 110, and often remains below 100. The local symptoms vary considerably and often are absent altogether. The most constant and early symptom, after temperature, is pain and tenderness referred to the bladder or kidney. Burnett[28] found tenderness in the costovertebral angle a valuable diagnostic sign. He also found abdominal distention frequently present, at times so marked that it was mistaken for intestinal obstruction. Sometimes there is evidence of a renal swelling or tumor on deep and careful palpation. Herpes labialis and urticaria have been observed in a few cases. In very acute cases we have the following picture described by Thompson as "well nigh pathognomonic, namely, sudden onset in an adult, with early cerebral symptoms, these soon passing with some into coma, but not convulsions, along with rapid rise of temperature and uncontrollable vomiting, a group of symptoms occurring in such sequence in no other renal derangement except those caused by invasion of the kidneys by some septic organism of which the colon bacillus is the most common."

The symptoms of chronic colon bacillus infection are impossible of enumeration, for, quoting Dudgeon and Ross,[29] they "may vary from a few apparently unimportant facts to a condition of considerable severity, while in some there is nothing to suggest from patient's symptoms that there is anything abnormal in patient's urine." As an example of chronic infection, Rovsing[30] reports the case of a woman, 65 years old, with colon infection of a number of years with recurrent acute nephritis. The last attack was septicemic, with coma and blindness in right eye from thrombosis. He used autogenous vaccine, and symptoms entirely cleared up. After an interval of six months there have been no recurrence of the acute nephritis. With such a clinical picture we must resort to the laboratory examination of the urine and blood to arrive at a definite diagnosis.

Dudgeon and Ross divide the urinary findings into the following types: "A. Urine quite clear, but on cultivation the *Bacillus coli* is detected. B. Turbidity of varying degrees; a bacilluria. C. Similar to type B, but with varying degrees of inflammation, as shown by a deposit of leucocytes. D. Pyuria and bacilluria. E. Pyuria, and on cultivation, the *Bacillus coli* is present." They describe the common reaction of the urine as acid, but say that it is more often alkaline than might be supposed, and that "in every case of bacilluria a centrifugalized specimen of the urine will show one or two polymorphonuclear leucocytes in a film preparation; in every instance the bacilli are mainly extracellular." "Here and there bacilli may be noted inside a polymorphonuclear cell, but not more than about 10 per cent. of the cells in the urine are phagocytic, and in these there are as a rule not more than ten or fifteen bacilli." From experimentation they found that it was "unusual for phagocytosis to occur to any extent in urine of patients suffering from either acute or chronic infection of the urinary tract due to the *Bacillus coli*. "The presence of blood in the urine is uncommon, and suggests that the colon bacillus is of secondary importance." Box[31] describes the urine as follows: "It is acid and opalescent, and when shaken it may show a 'mucous sheen.'" "When allowed to stand a slight sediment may fall; sometimes the sediment is rather abundant and consists of pus and epithelial cells, more rarely a faint mucous cloud separates, containing the bacilli in its meshes." He found that the opalescence of the urine is not removed by acids and boiling, the heat rather increasing the turbidity, owing to the precipitation of a small amount of albumin, which is often overlooked. He also finds filtration only diminishes the opalescence in so far as it removes the epithelial and pus cells, as the bacilli pass through. "Microscopical examination shows, in acute cases, pus and epithelial cells from various parts of the urinary tract, a few casts may possibly be recognized, and swarms of bacilli which are more or less actively motile." "The presence of casts points to infection of the parenchyma, but their absence does not prove that the kidney has escaped."

The ordinary routine urinary examination is insufficient for diagnostic purposes. The urine should be obtained under the most rigid precautions to prevent contamination, and the microscopical examination, as well as the culture, should be made from the centrifugalized sediment. One negative examination does not exclude the possibility of colon infection, as the specimen may have been obtained when the diseased kidney was secreting very little, if any, urine. At such a time the healthy kidney would be over-functionating, and the result would be a urine with very few, if any, pathological elements. A ureteral catheterization would obviate this difficulty, but in acute cases we are seldom justified in resorting to instrumentation.

Blood examinations are of doubtful significance as we have records of so few cases. Herringham says that the leucocytes are usually raised but reports that Lenhorlz has found them as low as 3,000 or 4,000. Dudgeon and Ross hold that while the opsonic and phagocytic indices of the patient's blood are low they are unreliable as aids to diagnosis. They found the agglutination test equally of no value and that normal human serum had no bactericidal effect on the colon bacillus. Davis[32] says "The fact that opsonification, bacteriolysis, and agglutination in cases of urinary colon infection do not run parallel is most readily explained by assuming the existence of specific opsonins, lysins, and agglutinins." I have been able to find but little in the literature on blood cultures in colon bacillus infection of the urinary tract. Until the condition becomes septicemic it is very difficult to find the *Bacillus coli* in cultures as it is only transiently in

the blood current. It has, however, been demonstrated in a few of these cases of localized infection.

In system infection we have the work of Coleman and Hastings,[33] who sum up their findings as follows: 1. Isolated reactions against *Bacillus coli communis* are without significance. 2. The blood serum in a case of infection by *Bacillus coli communis* may contain agglutinins for certain strains of this group, while the infection persists and not on the patient's return to health. 3. The detection of an increment of agglutinins in the blood serum for a particular strain of *Bacillus coli communis* is evidence of a local infection with that strain. 4. Some strains of *Bacillus coli communis* are capable of causing a disease clinically identical with typhoid fever.

Prognosis and Sequelæ: In all forms of colon bacillus infection of the urinary tract there is a tendency to spontaneous recovery, but in only about half does the bacillus disappear from the urine, the others pass a visible amount of pus for an indefinite time. In pyelitis of pregnancy there is a very low mortality and recovery usually takes place when the uterus is emptied. In abscess of the kidney the mortality is highest, but even in this condition we may have spontaneous recovery. In all acute cases there is the tendency for them to become chronic with acute exacerbations. Thomson regards "chronic interstitial nephritis as most frequently caused primarily by chronic infection of the kidneys by the *Bacillus coli.*" He also thinks that chronic colon infection may be the explanation of "numerous cases of human morbid conditions often of obscure origin such as progressive anemia with emaciation and nervous weakness often grouped under the vague term neurasthenia." Many people with a persistent albuminuria, with or without inflammatory elements in their urine, are suffering from chronic colon bacillus infection. The first knowledge they have that they are not physically sound is when they are refused life insurance. In many instances these people would be relieved of their so-called kidney disease by proper treatment.

Treatment: The treatment of colon bacillus infection of the urinary tract is absolute rest in bed and a bland non-stimulating diet, preferably milk, until all active symptoms have subsided. In convalescence a too rapid return to regular diet, especially when red meat is added, has been directly responsible for a relapse. In the subacute or chronic condition overfeeding or any indiscretion in diet has been the cause of an acute exacerbation of the infection. Drugs are given to produce free catharsis, to promote diuresis, to make the urine alkaline, antiseptic, and non-irritating. Diuresis is best accomplished by the free drinking of water, and in addition some of the simpler diuretics as spirits of nitros ether, ammonium acetate or citrate. The urine is made alkaline by large doses of potassium bicarbonate or citrate. Burnett[34] gives potassium citrate in 40 to 60-grain doses every two hours. The reason for an alkaline urine in the treatment of this infection was not understood until some recent observation. Houston, quoting Dick,[35] has shown that the ingestion of the *Bacillus coli* by leucocytes was much more active in an alkaline than an acid media. The value of urinary antiseptic drugs is in dispute. Pollock, Thomson, and Herringham hold that they are almost specific in their action. Box, Garnet Wright, and Dudgeon report no results from their use. Urotropin and sodium benzoate, 10 grains of each every three hours, have given me most satisfactory results in relieving symptoms, but in most cases have had but a temporary effect on the bacilluria.

Pardoe finds benzoate of sodium or ammonium with alkalies of value, but says that liquor potassæ should never be combined with benzoates. He finds that plenty of barley water, plain or with milk, or, better still, triticum repens (a wineglassful every two hours) will relieve the scalding sensation during urination. The best urinary sedative, in his opinion, is oil of sandalwood. Urotropin only gave him results in chronic conditions. Herringham says in some cases urotropin, the alkalies, and free water drinking is often sufficient to relieve symptoms.

Vaccines: The autogenous vaccines should be used when other means fail, as they are of value in many cases, although they are not the specific the early reports lead us to expect. There are reports *pro* and *con* and we shall review some of the more recent ones. Rovsing (1909) reports twelve cases of colon bacillus nephritis and pyelitis in which he used Wright's vaccine technique with a prompt cure in four cases when all other means had failed. He found that there was no effect on the proliferation of the bacteria in the urine and a very mild local and general reaction. Dudgeon and Ross (1910) in a series of a hundred cases report: "In a majority of the acute cases, which form a small proportion of the whole, complete recovery ensued, but in the case of those suffering from the chronic type of the disease complete recovery, *i. e.*, a sterile urine on more than one examination must be classed as exceptional." "In a large number of instances of pyuria and bacilluria associated with symptoms of various kinds, considerable improvement was effected; in some, conditions remained much as before, while those examples of pure bacilluria without symptoms, a few were treated, but the results as far as the condition of the urine was concerned must be regarded as unsuccessful." They found the best results from the use of 100 million to 200 million given every five days, and advise that the injection be made intramuscular and in different areas in rotation. In their cases a constitutional reaction of any degree was uncommon. Billings (1910) gives as an initial dose 200 million, gradually increasing until a decided local and general reaction is obtained. His maximum dose was one billion. In some cases he found it better to give small doses five million to one hundred million to prevent too great a reaction. He says "The specific effect of autogenous colon bacilli vaccine therapy is proven by the phenomena of reaction," which is both local and general. "The specificity is further indicated by an increase in the opsonic index, and finally by an immunity manifested by failure of reaction after vaccination and the disappearance of the bacteria from the urine." McCrea (1910) says that in those cases that do not respond to drugs, autogenous vaccines are most successful. He gives three million to a child one year old and twenty-five million to an adult every two days, gradually extending the time, depending on progress. Hartwell [36] (1910), basing his conclusions on twenty-five cases of pyogenic infections of the urinary tract, treated with vaccines, says that vaccines are indicated in acute pyelitis, which does not respond well to ordinary measures, and in cystitis they appear a less troublesome and possibly more rapid means of cure than irrigation and urinary antiseptics. Geraghty [37] (1910) in a series of thirteen cases of various urinary infections, the majority of which were due to *Bacillus coli com-*

munis in pure culture or mixed with other organisms concludes as follows: 1. "An autogenous vaccine was prepared in each case and doses ranging from 200 to 800 million were employed. No reaction whatever was noticed from the large doses. 2. All the patients were treated over a long period of time from three to twelve months. 3. In not a single instance was any improvement produced which could in any way be attributed to vaccine therapy." Williams, Cragin, and Newell[38] (1910) in a report on vaccines in gynecology and obstetrics say: "In infections of the urinary tract, especially those due to colon bacillus, it sometimes results in symptomatic cure, but rarely relieves the bacteriuria. The scant reports concerning pyelitis and pyelonephritis of pregnancy indicate that vaccine therapy is no more efficient than the usual treatment by rest in bed and the administration of salol and urotropin, as in neither does the bacteriuria disappear until after the termination of labor." Schwarz[39] (1910) in an article on "Serum Therapy and Bacterial Vaccines in Treatment of Puerperal Septicemia" makes the following observations: "1. Employment must be based on bacteriological diagnosis. 2. In the more localized infections, such as those of urinary tract by the colon bacillus, pelvic inflammation caused by gonococcus and various staphylococcus infections, vaccine treatment has a legitimate field and can accomplish much good. In acute affections of any kind the use of bacterial vaccines is contraindicated." Cabot[40] (1911) in a series of thirty cases, of which twenty-two had pure colon bacillus infection and in three others colon bacillus mixed with streptococcus or staphylococcus concludes: "1. The use of vaccines is followed by improvement of symptoms in more than half the cases. 2. Vaccines have little effect on bacteriuria. 3. The results are practically the same whether the lesion is in the upper or lower urinary tract."

Serum: Dudgeon and Ross find excellent results are obtained in acute cases by the use of anti-*Bacillus coli* serum, given in doses of 25 c.c., spread over seventy-two hours. The patient must remain in bed for a week during this treatment. They also warn us that great care should be taken to ascertain that patient has not received serum treatment for this or some other affection at a more or less recent date. In acute cases during pregnancy and in old people it is better to use vaccines because of the severe constitutional symptoms which follow serum treatment. They also find that in the late stages of acute cases when serum is supplanted by vaccines there is often distinct benefit noticed.

Topical Applications: Most observers are opposed to any instrumentation except in chronic conditions. Rovsing finds that the bacilluria is relieved by using a retention catheter, washing out the bladder with sterile water, and giving salol while administering the vaccines. Box reports that Dudgeon found by washing out the bladder with anti-*Bacillus* coli serum there was produced a marked but temporary diminution of the bacilli. He also says that Shattuck and Dudgeon have at present (1910) a scheme for acclimitization for the lactic acid bacillus in the urinary passages in hope that it may expel the colon organism.

Surgery: We should use all other means within safety before resorting to surgical interference. The definite indication is when the kidney or surrounding structures are so far involved that they endanger life. Even in multiple abscesses of the kidney, recovery sometimes takes place spontaneously. Furthermore, surgery may only relieve the result and not the cause, and later we are confronted by a similar condition in the other kidney.

During the past two years I have had the opportunity of observing quite a number of colon bacillus infections of the urinary tract. These cases, with others, I may observe, I hope to report at some later time. From a study of these cases and a review of the literature, I draw the following conclusions.

1. In a certain percentage of adults, even in health, the *Bacillus coli* is taken up by the lymphatics and blood vessels of the intestines and deposited by the blood current in the kidneys. The number and virulence of these microorganisms depend on the intestinal disturbance and the particular strain present.

2. The greatest predisposing cause of *Bacillus coli* infection of the urinary tract is anything that interferes with a free secretion of urine or causes any back pressure in the urinary tract.

3. The earliest symptoms of *Bacillus coli* infection of the urinary tract are apt to be mistaken for those of a mild cystitis, whereas the real site of infection is most often higher up in the urinary tract and of more serious pathological import.

4. With greater care in diagnosis we will find that *Bacillus coli* infections of the urinary tract are likely to be mistaken for other acute conditions, such as appendicitis, malaria, intestinal indigestion, toxemia of pregnancy, ether nephritis, and acute and chronic nephritis. This is especially true of post-operative gynecological cases

OBSERVATIONS IN FOUR CASES OF CHRONIC DYSENTERY NON-AMEBIC IN NATURE.

By ANTHONY BASSLER, M.D.,

NEW YORK,

VISITING GASTROENTEROLOGIST TO THE PEOPLES HOSPITAL AND CHIEF GASTROENTEROLOGIST TO THE GERMAN POLIKLINIK.

Dysentery has been divided into the acute and chronic forms; the acute due to infections by the Shiga bacilli or the allied strains identified by Flexner, Kruse, Park and Hiss, and the chronic to the ameba and perhaps to less known members of the colon group than the first- mentioned ones.

In the temperate climates chronic infections of the lower intestinal tract are met with in adults in which the causative organisms are neither the ameba nor those classed in the acute forms of dysentery—they being the true dysentery bacilli and the mannite-fermenting forms. It is very probable that most of these cases are today being described under the clinical terms of "chronic colitis" and "ulcerating" or "follicular colitis, "chronic diarrhea," and otherwise, the bacterial etiological connection of which has received but scant attention. The bacterial observations on four of such cases are reported here, the history of only one being presented in full.

Caes I.—Dentist; 31 years; father died of apoplexy at 65, mother living; habits good. Previous history—had measles and chickenpox as a child, and no illness worthy of note up to the present one, but never had been physically strong and always was underweight. Present history—twelve years ago began with gastric pains of an indefinite character and rather constant distress in the upper abdomen, both of which were independent of meals. With periods of remission, he continued up to five years ago, when his bowels became noticeably loose, he passing considerable quantities of mucus, which sometimes was blood streaked, and at times bright blood was voided with the stool. Beginning three and a half years ago and continued for a period of six months, he had normal movements and then again the characteristic discharges above described. At this time his condition was diagnosed as "ulcerative colitis" and an appendicostomy was performed and daily irrigations of the colon from the caput downward by means of saline solution were carried on for three months. For two and a half months subsequent to this treatment his bowel movements were normal—he having about two each day without noticeable mucus or blood. The symptoms of large amounts of gas formation, colicky pains and the diarrheal movements with mucus and blood then returned so that in one week his condition was about as before the last treatment. He was then placed on a fat free and low starch diet with some measure of benefit, but the dysenteric condition was always present. This diet was maintained for one year, at the end of which time the condition became worse than it had ever been. At this stage a diagnosis of prolapse of the abdominal organs was made and the wearing of an abdominal support (belt) advised. No benefit accruing therefrom, extirpation of the colon was suggested, but refused. Colonic irrigations with thymol solutions were then tried with slight benefit (probably not more so than would have been gained by any other form of daily colonic irrigations). At the time when he was first seen by me, he had had a steady dysentery for seventeen months, no special treatments and only some slight dietetic attentions having been carried out.

Examination: Pale, emaciated, muscles soft, nervous mien, heart and lungs negative, abdomen slightly distended, stomach and intestines low, liver just palpable, but not enlarged, manual gas displacement evident in the ascending and transverse colon, marked gastric splashing; chronic proctitis, rectal dome and lower portion of the sigmoid markedly congested with areas of attached mucus and a superficial ulceration in the sigmoid about 2 mm. in diameter; blood pressure 127 mm. Hg.; weight 112¾ lbs. Laboratory: Blood color index .8, Hb. 72 per cent. erythrocytes 4,050,000, morphology normal, leucocytes 7,200, differential count normal; urine* normal, excepting slight albuminuria, uric acid 1.1 gram, total sulphates 2.4 grams (preformed 2.09 grams, conjugate .31 gram), indican high; stomach contents normal (mixed test-meal used); feces* semifluid with blood-streaked mucus, acid reaction, many meat fibres and albumin loss above normal, putrefaction gas result low, bacteria 41 per cent of stool and Gram differential stained slides of the raw feces showed mostly negative organisms of the colon type, all of the negative bacteria being about 72 per cent. of the two types.

The report of the above case answers for the other three also, all of which were in men, with these notable differences. Ages, 37, 44 and 45. One had had typhoid fever seven years before the dysentery history began. In one the dysentery was of four years' standing, the next five and a half, and the third eleven years, all having periods of remission during its course. In one the blood examination showed a more decided anemia, although in the other two it was nearer to normal, one, however, having a leucocyte count of 9,750. One had a mitral blow, probably organic, with slight cardiac

*The urine and feces were collected under these conditions: After an enema to cleanse the lower colon, capsules of carmine were given by mouth to demarcate the stools. The patients were placed on the following diet, and after the carmine had been noted in some subsequent stool the entire next stool was used for examination together with the total output of urine in the twenty-four hours representing the day in which the stool had been obtained. Diet: Morning, two thin slices of well-baked bread with butter liberally applied; one pint of oat meal gruel, made of about 1½ oz. or 45 gm. of oat meal, ½ oz. or 15 gm. of butter, 6 oz. or 200 c.c. of milk, 8½ oz. or 265 c.c. of water, and one egg. 11 A. M., milk, one pint or 500 c.c. Noon, a good sized piece of steak or roast beef chopped or cut into very fine pieces (about 4 oz. or 125 gm.) and served on a slice of toast; one bowl (about 8 oz. or 250 gm.) of mashed potatoes with ¼ oz. or 15 gm. of butter. 4 P. M., milk, one pint or 500 c.c. Night, same diet as for breakfast.

hypertrophy. All were emaciated, and had the characteristic urine and feces described.

The reason of the observations in these cases was to note if possible whether there was anything distinctive in the character of the organisms predominant in the intestinal canal of the cases—which apparently were of the colon group. For this purpose loops of the mucus adherent to the upper rectum and sigmoid and scrapings of the ulcer bases were used in the examinations and the inoculating material in the culture work.

In each instance it was evident that the *B. coli communis* was the infecting organism, the mucus being charged with them, and in the ulcer scrapings it was shown that these organisms had gained entrance into the tissue walls of the gut and were living and probably proliferating there. Scrapings from the mucous membrane of the upper rectum and colon in seven healthy persons did not show the presence of the *B. coli communis* within the tissue of the gut wall when proper precautions had been exercised in the scrapings. In each of the cases the organisms grown in culture were Gram negative, flagella were noted in the form from one (not from the other three), they were non-liquefying, grew readily on all of the culture media (and characteristically in large opaque colonies on the gelatine and most abundantly on potato), produced organic acids in milk, fermented glucose solutions with the production of acid and gas, and did not produce indol in ordinary nutritive broth (two of them did in Witte peptone solution), and the intraperitoneal injections of the bacteria grown from all of the cases were fatal within four days to a rabbit, guinea-pig, and cat in each instance—all of the animals dying within 50 hours, excepting a cat, which lived 93 hours.

It was this definite pathogenesis in lower animals (in which it was evident that these organisms were more regularly fatal than is one's experience with the usual forms of *B. coli communis*) that suggested the making of agglutinating reactions with the serum and organisms from the cases with controls of those of other strains in the hope that some facts might be gained in identifying the type of organism at work in the condition. In each instance it was found that the serums from these individuals agglutinated their own strain of organisms more definitely than they did the *B. coli communis* obtained from innocent sources; still it was evident that the blood of these patients agglutinated the *B. coli communis* of innocent forms more actively than did the blood serums of normal individuals—this being manifested in seven cultures from different normal persons (swabs of the high rectum and scrapings of the sigmoid membrane and the separation of the *B. coli communis* used to obtain the innocent forms). The bacterial deductions from the observation of these cases suggested the following:

1. That there is a chronic form of dysentery due to the *B. coli communis*, and that these cases are not uncommon in the temperate climates.

2. That the form of infecting organisms does not correspond to the Shiga or the mannite-fermenting types, and that they are not possible of differentiation from the known forms of *B. coli communis* of high virulence.

3. That the serums from the cases strongly agglutinated the organisms obtained from that person and more definitely than they did the strains of *B. coli communis* obtained from innocent sources.

4. That the organisms were most fatal to lower animals, decidedly more so than in one's experience with the human *B. coli communis* ordinarily obtained and used in laboratory observations.

5. That the organisms existed in large numbers in the lower intestinal tract of the cases, mostly in the mucus, and that they are capable of destruction of tissue locally with the production of ulcers and then living within the tissue of the gut wall in the bases of them.

6. That in the etiology of these cases we are dealing either with a definite organism of the *B. coli* group, or with *B. coli communis* of a high virulence, strongly hemiparasitic in nature and from which the aggressin production is overwhelming and against the effects of which in susceptible individuals the body cannot resist local tissue infection.

7. That the clinical entity "Chronic dysentery due to the *Bacillus coli communis*" seems warranted, and further that there is reason for the belief that in the production of this disease we are dealing with an organism of the colon group specialized in nature.

A NEW THERMO-THERAPEUTIC METHOD IN GYNECOLOGICAL CASES.

By S. FLATAU, M.D.,

NUREMBERG, GERMANY.

THOUSANDS of years ago the therapeutic instinct recognized the heating properties of warmth and added them to its stock. But the employment of heat as a therapeutic measure founded on scientific principles dates from the time when August Bier collected, extended, and enlarged the earlier works of physiologists and pathologists in his system "Hyperämie als Heilmittel."

As a matter of course gynecologists too were desirous of securing the advantages of hyperemic treatment in their special branch, the employment of warmth appearing to be particularly suitable in these cases. The female genital sphere is locally rather sharply defined, and the accessibility of the interior genitals through the connecting vagina favors the introduction of heat. Finally, according to the researches of Goldscheider (*Archiv für Psychiatrie*, 1887), the abdomen seemed specially adapted to the stimulating properties of warmth on account of the numerous nerve ends susceptible to heat which it contains (Ruffini termini). We know, indeed, that warmth exercises an expanding effect on the vascular system and that the amount of blood in the skin operates on the neighboring, deeper-lying vessels in producing a more rapid exchange (Matthes, "Klinische Hydrotherapie," 1900). As a matter of fact, the subcutaneous cellular tissue—which is mostly well developed—by its low conductivity demonstrated by Fuchs (*Zeitschrift für Biologie*, vol. x, p. 73) forms a great obstacle to the penetration of heat when we desire to apply it only through the skin. But on the other hand, through the extraordinarily decreased speed of the blood in the pelvic venous system, we have the guarantee that the heat will not be too rapidly dispersed or lost; in fact that it accumulates. In addition to these premises we have the fact that the stimulating effect of heat therapy increases in a certain degree parallel with the temperature and the duration of the application.

Strictly speaking, the first applicable thermo-ap-

paratus was that produced by Polano (*Zentralblatt für Gynäkologie*, 1901, No. 30) while working side by side with Bier and Klapp in Greifswald, and which he constructed as a hot air apparatus. Hot air, up to a temperature of 100° C. (212°F.), was

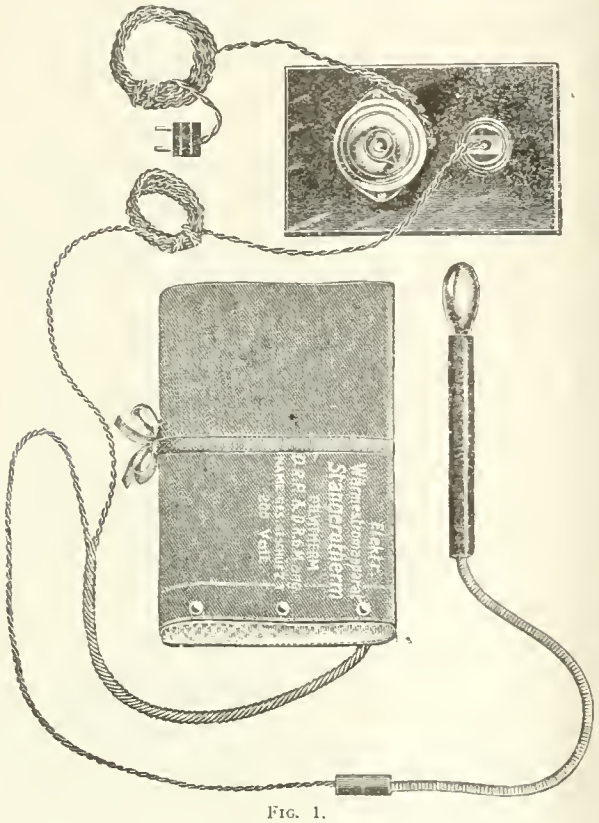

Fig. 1.

circulated round the abdomen of the patient, the abdominal regions being enclosed in a wooden case. But in spite of the excessive heat registered by Polano's thermometer, the temperature of the pelvic contents was very slightly affected, for heat which is applied to the skin penetrates only to a very small extent.

Neither was the problem of raising the pelvic temperature solved by the kataplasma ovens, heat boxes, and so-called thermophores, with highly saturated solutions of acetous sodium. But all these methods of applying heat are too evanescent in their results. Even if 20 pints of hot water are passed through the vagina, still the rise of temperature in the pelvic organs is practically nil; apart from which all these processes require too much attendance, etc.

Therefore the idea of Mirtl (*Wiener Med. Presse*, 1899, No. 16) and Stehlik (*Münchener med. Wochenschrift*, 1899, No. 27) to construct a thermophore in the form of a "colpeurynter" filled with thermophore salts, to be introduced into the vagina. Unfortunately the heating effect in this case is also insignificant, and the stock of heat in the thermophor decreases continuously instead of remaining constant. To produce a source of heat which would remain constant was the problem to be solved in heating the pelvis. Its practical solution was made possible only by the improvement in thermoelectric apparatus. When I first saw the electric thermophore cushions, as made by the firm Heinrich Stanger, in Ulm, a solution of the problem immediately occurred to me. I had a thick hollow rod made out of silver-plated metal, which ended in a sort of bulb (see Fig. 1). Within this there is a mass of asbestos powder, which is heated by passing an electric current through it. A small indicator makes it possible to increase or decrease the degree of temperature with sufficient delicacy.

The practical tests, which I at once made in my private clinic, answered the requirements which are expected of an apparatus for heating the pelvis. During the applications the pelvic contents were always raised several degrees in temperature, that is the pelvic organs were really heated. My experiments were still more successful when the introduction of the instrument into the vagina was combined with the application of an electrothermophore covering the abdomen. Through the vicinity of two hollow organs, the bladder and the rectum, we have a good opportunity to measure the increase of temperature and the influence of the heat introduced into the pelvis. Numerous measurements were made in this manner, and the temperatures were read on thermometers introduced into the bladder and rectum. Here I give the averages of a very large number of readings:

	After 1 hour,	2 hours,	3 hours,
Bladder.....	38.8°	39.8°	40.2°
Rectum.....	38.5°	39.2°	39.8°

The readings are expressed in degrees Centigrade.

The mode of application is the simplest imaginable. My apparatus can be connected with any switch contact or any electric lamp, either to a continuous or an alternating current. The regulation of the heat introduced, as shown by the indicator, is best attended to by the patient, whose best guide is her subjective sensations. There is no deposit of perspiration on the abdomen; the heat is absolutely dry. We know that, objectively considered, dry and damp heat are totally different phenomena and subjectively, too, are differently felt; and this indeed, in that dry heat is more agreeable to by far the most patients. My patients supported the process in all cases excellently. In other parts of the body, especially the breast and head, there was a sensation of increased temperature; perspiration also appeared. Although the thermometer in her axilla showed no increase of temperature in the body as a whole, increased activity of the heart and lungs (breathing) was observed, but this was not pronounced enough to cause the patient inconvenience. If one examines the vagina and the cervoix uteri shortly after an application of my thermal processes, one will find signs of hyperemia and supersecretion of a markedly high degree.

The diseases in which my apparatus is indicated are numerous, although greater experience is neces-

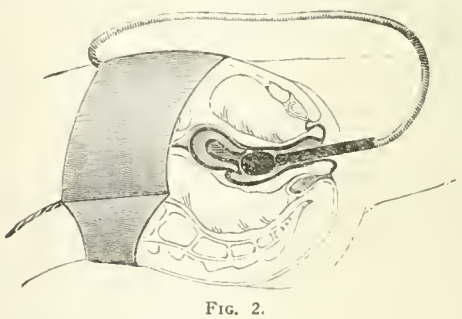

Fig. 2.

sary before drawing hard and fast lines. All chronic diseases of the para and perimentrium, chronic catarrh of the uterus and Fallopian tubes, so-called chronic metritis, exudation remains, dysmenorrhea without evident cause, amenorrhea in

cases of uteral atrophy during nursing have all shown symptoms of improvement under thermopenetration. Catarrh in the bladder of long standing has also been favorably influenced. On the other hand, the method is out of place in treating cases where there is fever; all diseases of the adnexa in which pus is present, or may be expected to form, and tuberculosis of the genitals. As is well known, the gonococcus is hypersensitive to high temperature, hence diathermal experiments in cases of infection with Neisser's diplococcus would probably be attended with success. Usually I apply the instrument for three hours daily, although, of course, there is no reason why this duration should not be increased. The temperature of the pelvis falls very slowly after the instrument is removed, so that the tissues assume their normal temperature only after one or two hours.

I demonstrated my apparatus before the Franconian Gynecological Society on October 24, 1908, and spoke then of the extent to which it may be employed.* This I wish to emphasize because the whole idea was evidently in the air during the development of our electrotherapeutic methods. I mean the idea of diathermy, the thermopenetration of segments of the body. Thus Sellheim described eighteen months later in the May number of "*Monatshefte für Geburtshilfe und Gynäcologie*," vol. xxxi, a process in which the temperature of the pelvic organs was raised to 40° and 41° C., by passing the so-called high-frequency current (de Forrest current) between two electrodes. For the present, however, there are two arguments against their general employment. Firstly, we still know too little concerning the physical and biological effects of the high-frequency current on the living tissues. Secondly, Sellheim's apparatus is too costly.

Next Feis, in Frankfort, without knowing anything of my first publication, announced his kolpotherm (*Münchener med. Wochenschrift*). In this instrument a small electric lamp is enclosed in a metal case and introduced into the vagina. Compared to the fragile carbon wire and glass case in Feis' kolpotherm, my device has the advantage of being absolutely unbreakable, and can be used for an unlimited length of time.

In conclusion I will recapitulate:

1. This vaginal heating instrument, "pelvitherm,"† raises the temperature of the female pelvis up to about 40° C. for any length of time.

2. Its use, in contrast to all other existing methods, requires no special superintendence, and therefore does not take up the time of the clinic staff.

3. It can be used anywhere where electric light is in use, as well as in the patient's home.

4. The instruments are so cheap and lasting that every hospital or private practitioner can procure a number of them.

I am recommending this diathermic method for application and test because it answers all the requirements of a practical, rapid and agreeable therapy.

*See official report in No. 2 *Münchener med. Wochenschrift*, 1909.

†Heinroth Stanger Ulm a. D. Germany.

Winckel's Disease.—Brandenberg supports the contention of Baginsky that icterus neonatorum, Buhl's and Winckel's disease are all different stages of the same process. The hemolysis caused by the infection (regarded by Czerny as of intestinal origin) produces an abnormally large amount of bile, which explains the icterus.—*Archiv für Kinderheilkunde.*

THE MASTERS OF MEDICINE AS EXPONENTS OF MEDICAL IDEALS.

By W. B. KONKLE, M.D.,

MONTOURSVILLE, PA.

In the *Déontologie Médicale* of Dr. Max Simon is set forth this device for medicine—"*Vérité dans la science et moralité dans l'art.*" A high mark that, indeed. And yet does the legend imply naught of exaggeration or untruth. Medicine has ever cherished and professed aims pure, dignified, noble—has ever been actuated by the Emersonian precept, "Hitch your wagon to a star." *Ever?* Yes; even the most distant voices that have spoken of healing, and whose tones still "echo down the corridors of time," ring true to righteousness and honor. And from age to age down to us of the living hour has the tradition been passed the same and inviolate. From the very beginning, and thereafter always, howsoever crude and imperfect otherwise medicine challenges respect and admiration by its ideals and motives; howsoever weak upon the sides of knowledge and practice it has, nevertheless, been constantly and invariably strong upon the side of moral principle.

And all this is so despite the fact that doctors alone and as a body have been nothing other than human—have lived and done much like the people about them—have, perhaps, reflected in any given social epoch the prevailing general ratio of good to bad. No class of men, not even the sacerdotal, has shown itself possessed of seven-league boots in the march along the road of practical virtue—the whole crowd keeps rather closely together in the forward movement. Now and then, forsooth, some choice soul outstrips the plodding masses. Such a life endures, an inspiration, a vindication of the ideal.

It should not be expected that doctors in character and conduct average much above the society of which they are components. Lapses from rectitude upon their part are to be judged by co-existing standards. Apollonides of Cos was guilty of a criminal relation with the widow of Megabyzus, to whose family he had been physician. But the Persian court was malodorous from like affairs. Eudemus maintained a scandalous *liaison* with Livilla whose husband, Drusus, he poisoned. Vectius Valens was one of the paramours of the abominable Messalina. Xenophon of Cos finished for the infamous Agrippina the poisoning of Claudius, the which delicate job had been botched by the notorious Locusta. But these things occurred at Rome when Rome was rottenness. Asclepiades of Prusa was a semi-charlatan exploiting the maxim, "*Mundus vult decipi*," at a day when in the Eternal City imposture was rampant. Avicanna died at 57, the victim of women and wine, when sensuality and luxury were sapping the foundations of the Arabian Empire. Paracelsus was a drunkard when bouts of drunkenness were the common pastime of high and low. John Brown was the base slave of alcohol and opium; but even now is that condition nothing rare in Scotland and England—and elsewhere.

And doctors have not been wholly free from bigotry. They have, indeed, manifested betimes the grossest intolerance of reform and progress. The greatest hostility toward improvement and advancement in medicine has been encountered within the medical fold itself. Such pathfinders as Paracelsus, Vesalius, Harvey and Jenner have at every move and turn found themselves confronted by the swords of their brethren. But in all their hanging

back and holding back doctors have been markedly conscientious. It has been a question of lack of light. Honesty unillumined is a blind gladiator. Conscience operating in God's open day is a true and worthy master. But there is no tyranny more stern, more inflexible, more inexorable than the tyranny of a benighted conscience. Liberty is a daughter of the sun.

Let us take a cursory glance at medical ideals in order that we may afterward notice how these are bodied forth in the expressed thought of the master minds of medicine from the earliest times on through the centuries. The doctor should be richly endowed in body, mind and heart. He should have soundness, vigor and endurance. He should be an upright man. He should be gifted with keenness of perception, clearness of reason and accuracy of judgment. He should be shrewd, tactful, cautious. The doctor's eyes should be *x*-ray eyes; his ears should be the ears of the Scandinavian god, Heimdal, who could hear the grass grow; and a special divinity should be the god of silence—Horus, the beautiful boy sitting in a lotus flower, his finger placed upon his lips. In truth, one of the best of working mottoes for the doctor would be, Eyes and ears open, and mouth shut.

The doctor should be a humane man. The traditions, the spirit, the genius of medicine are all for life-saving—to all these is the taking of life contrary. Of course, in his efforts to save again and again the doctor fails—he is not omniscient and he is not omnipotent. But first and last he tries to be a healer and a savior.

The doctor should be a broad, great-minded man. One of the best and most illustrious of Rome's emperors the eve of the night in which he died gave his guard the watchword, "*Æquanimitas.*" But there is something grander and nobler than equanimity, and that is magnanimity—the former is more egoistic, the latter more altruistic.

Finally, the doctor should be unfalteringly loyal to duty. To him "ought" and "ought not" should be as imperative and as inevitable as "must" and "must not." What a fine, royal fellow is the doctor who never flinches!

And now for the testimony as to these matters of some of the saints of medicine. We shall begin with the medical writings of the Hindoos, selecting passages from the Ayur Veda whose authorship is by legend attributed to Brahma, and whose date is assigned to somewhere between the fourteenth and the ninth century B. C. This about the medical teacher—"He should be kind and humble to everyone; he should always be ready to expose the good rather than the bad qualities of others; he should be clean and neat in his person; he should always be increasing his knowledge of books, and should be neither angered by the improprieties of others nor fatigued by their importunities. He should be kind and considerate to his pupils, and be able to explain the most complicated statements in the simplest and most perspicuous language." This about the medical student—"He should be inquisitive and observant, not covetous, jealous or lazy; he should be a philanthropist, possess a generous heart, and his disposition should be amiable and happy. He is to be taught to be chaste and temperate, to speak the truth, and to obey his teacher in all things." This about the physician—"He should preserve a healthy body; he should keep his nails and beard short, his body pure, his clothes clean. He should avoid especially any familiarity with women. Transactions in the house should not be bruited abroad. Money will be the recompense bestowed by the rich; friendship, reputation, increase of virtue, prayers and gratitude will be that of the poor."

In Egypt medicine was very closely bound to priestcraft, its teaching being conducted in the magnificent sacerdotal schools. Physicians being at the same time priests were subject to all the strict regulations of habit and life prescribed for the latter, and were imbued with their sublime philosophy and noble precepts. Here is an exhortation to a student—"Give not thyself to idleness, or thou shalt be smartly chastised; abandon not thy heart to pleasure, or thou wilt let thy books slip out of thy hands; practice conversation; discuss with those who are wiser than thyself; do the works of an elevated man. Neglect not thy books; do not take a dislike to them."

We must not pass by the great Greek schools of medicine, the schools of the Asclepiads, chiefly because to them belonged the so-called "Hippocratic oath." It is quite certainly known that Hippocrates was not the author of this famous formula—better had it been called the oath of the Asclepiads. Upon completing their course at Cyrene, or Crotona or Cnidos or Cos, or elsewhere, the pupils were obliged to take this oath. Hippocrates himself had doubtless subscribed to it, and as surely imposed it upon his own disciples. It is so well known that quotation may be omitted. The clause referring to the seduction of males, free and enslaved, would reflect discredit and shame upon the guild did its expediency not proceed from the fact that pederasty and sodomy had fastened themselves like a cancer upon lovely Greece, the imputation of their taint clinging to the memories of even Sophocles and Euripides, and the apology for their existence persisting as a foul blot on the immortal pages of Plato. Noble oath of the Asclepiads! Upward to the stars soars the name of medicine on the pinions of the vow, "With purity and with holiness I will pass my life and practice my art."

And now we come to Hippocrates, *our* Hippocrates, our lord and master, protagonist and paragon of physicians. Hear him—"Art is long and life is short, opportunity fleeting, experience deceptive and judgment difficult. The physician is a servant, not a teacher of nature. He must know what his predecessors have known if he does not wish to deceive both himself and others. The physician should be neat as to his dress, serious in his manners. He should be moderate in all his actions, chaste and reserved in the intercourse which he is obliged to have with the other sex. He should be neither envious nor unjust, nor love dishonest gain. He should not be a great talker, but it is necessary, nevertheless, that he should be ready to reply to everybody with mildness. He should also be modest, sober, patient, prompt to do his whole duty without anxiety; pious without going so far as superstition, conducting himself with propriety in his profession and in all the actions of his life. In a word, he should be a good man, and have at the same time the prudence and industry requisite for the efficient exercise of his art. As to the fee owed to the doctor, he should act in this connection with probity and humanity, having regard for the ability or inability of the patient to recompense him more or less liberally." A delightful Grecism is Hippocrates' short definition of a physician—"An upright man instructed in the art of healing."

Crossing the time equator of our Western peoples, Galen looms into view, a colossal figure, to whom appertained the undisputed autocracy of medicine for a thousand years and longer. Renouard says of him that, "for erudition, subtilty of reasoning, universality of information, he yields to Aristotle alone, over whom otherwise he bears away the palm by elegance, purity and force of style." Galen's father was the good and learned Nicon, who imparted to the son these lessons—"Do not give yourself up rashly and blindly to any sect. Sects are implacable despots; to accept their thraldom is to take away from one's actions and thought all liberty. Be just, temperate, courageous, prudent; flee immoderate desires; seek the truth before all else; remain in everything consistent with thyself, immovable in thy principles, firm in thy resolutions." Concerning himself Galen says this—"Neither the abuse of men, nor their injustices, nor the loss of honors can alter the peace of my soul. I have saved myself that degree of humiliation which I should suffer were such incidents able to divert my mind from the path of reason. It concerns me little to please men. I am affected neither by the flatteries of some, nor by the censure of others. I do not think of securing the good graces of all people any more than of possessing all things." Says Galen again—"The good physician should practice with disinterestedness, not for money, but for the good of humanity. It is not possible to covet riches, and at the same time to cultivate worthily medicine, that art so noble; if a man devote himself ardently to one, he will neglect certainly the other. How could he love labor who besots himself, who gorges himself with various foods and delivers himself to the pleasures of Venus, who, to put it in a word, is the slave of his belly and his wanton inclinations! It remains then established, that the true physician is the friend of temperance, and that he is, at the same time, the disciple of truth."

The Arabian period presents a group of highly illustrious philosopher-physicians. Of these one of the most eminent by reason of his talents and attainments was Rhazes, the cithern-player. From him is this upon the choice of a physician—"Inform yourself with care upon the antecedents of the man to whom you design confiding that which is the most dear to you in the world—namely, your health, your life, the health and life of your wife and children. If this man dissipates his time in frivolous distractions, in pleasure parties; if he cultivates with too much curiosity the arts foreign to his profession, as music, poetry; more important still, if he is addicted to wine, to debauchery, beware of committing into such hands a deposit so precious. He alone merits your confidence who, having opportunely applied himself to the study of medicine, has frequented able masters and seen much of the sick; who joins to the assiduous reading of good authors his personal observations. For it is impossible to see all, to test everything one's self; and the knowledge, the experience of a single individual, compared with the knowledge, with the experience of all men and of all ages resembles a thin thread of water placed beside a great river."

Guy de Chauliac is honored with the title of father of surgery. Portal declares that he "said nearly everything which modern surgeons say." This is from his *"Chirurgia Magna"*—"The surgeon should be learned, skilled, ingenious and of good morals; be bold in things that are sure, cautious in dangers; avoid evil cures and practices; be gracious to the sick, obliging to his colleagues, wise in his predictions; be chaste, sober, pitiful and merciful; not covetous nor extortionate of money; but let the recompense be moderate, according to the work, the means of the sick, the character of the issue or event and its dignity."

Fernel, the consummate medical scholar, great of mind and great of heart, for generations through his written work was a teacher of medicine. One of his utterances in this—"Medicine, the eye always fixed upon nature, and, as it were, made in her image and resemblance, takes her law for guide, studying and bending every effort to imitate her, in order to preserve man's health constant and exempt from maladies, to restore and re-establish it when it totters and becomes deranged, finally to prolong life itself sound and safe as long as it is possible."

Paré is a beacon-light that shines and shines undimmed and uneclipsed—a pure white light that charms, but never deceives. At a day when it was usual to keep as a secret any medical or surgical discovery we find this prince of surgeons affirming thus—"For my part, I have shared freely with all persons the gifts which God has conferred upon me. And for that I have not the less; just as the luminosity of the candle is no whit diminished although many come to it to light their torches."

Sydenham is a fixed star in the medical firmament—aye, a lodestar. Plain, unvarnished wisdom is characteristic of him—here is a piece of it—"All those hypotheses which are the products of the imagination and do not repose upon observation will be overthrown and destroyed by time; while the judgments of nature will not perish except with nature herself. If one pretended that hypotheses might serve as a basis for medical practice, such an idea would not be less absurd than that of an architect who should wish to construct the first story of a house before laying the foundations. This constitutes what is called building castles in Spain, but it is not to observe nature."

Let us end our list of references with the German physician-philosopher, Stahl. Sincere, earnest, profound, he was essentially and peculiarly idealistic. As a representative message from him, we select this—"In reality, the physician who loves and cultivates wisdom is almost divine, that is to say, almost like a god; for all which has affinity with wisdom is found, also, to make part of medical morality. Such are, in fact, contempt for money and for gain, modesty and respect, absence of ostentation in clothing, a good reputation, a sound judgment, a just appreciation of things, mildness, amenity, activity, politeness, cleanliness, a precision in language, the art of distinguishing the things which are most often useful and even necessary to life; in order that, by an intelligent discretion, the physician-philosopher may be able to shelter himself from the fear of reverses of fortune to which are exposed the avaricious and the superstitious."

We have gone far and fast, and have made but few and short stops. The journey accomplished more leisurely and by easier stages might have afforded greater pleasure and profit. Yet, nevertheless, have we not been treading upon holy ground? And have we not been breathing celestial air? Truly such voices from the past are refreshing, invigorating, inspiring. From such lofty communion there comes a new sense of dignity and honor. Should there not, also, come added feeling of responsibility and obligation? Should there not come

deeper purpose to climb as near as in us lies to medicine's ideals? Should there not come stronger resolve that medcine's high-flung standard shall not sink?

"Wherefore seeing we are compassed about with so great a cloud of witnesses, let us lay aside every weight, and the sin which doth so easily beset us, and let us run with patience the race that is set before us."

THE TREATMENT OF TETANUS.*

By J. NORMAN HENRY, M.D.,

PHILADELPHIA, PA.

CLINICAL PROFESSOR OF MEDICINE, WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA; PHYSICIAN TO THE PENNSYLVANIA HOSPITAL; ASSISTANT PHYSICIAN TO THE PHILADELPHIA HOSPITAL; FELLOW OF THE COLLEGE OF PHYSICIANS.

I CAN well remember the first case of tetanus I ever saw, and my surprise at its fatal termination. The case was that of a woman who was admitted to the Pennsylvania Hospital in 1896, suffering from a well-marked, but apparently mild tetanus. She was taken to a remote room in the attic and there isolated in order to secure quiet for herself, as well as for the patients in the general ward. The visiting physician, on making his round, examined the patient, concurred in the diagnosis, and prefaced his directions as to treatment by remarking that of course the patient would die, as did 99½ per cent. of all such cases. This woman seemed to do well for some days, having but moderate trismus, retraction of head and arching of the back, while the clonic convulsions were almost entirely limited to the small electric-shocklike contractions so commonly seen in tetanus. After a week or so the patient died of exhaustion and toxemia, which we were unable to relieve in any way by our treatment, which was directed solely toward the mitigation of the symptoms, as at that time no specific therapy had been attempted.

I quote this case because of its similarity in course and termination to a majority of those of acute tetanus, and because also it furnishes a good illustration of the difficulty of forming a prognosis and any opinion as to the efficacy of treatment in an individual case. This patient seemed but mildly ill, had little fever, few if any major convulsions, and not sufficient locking of the jaws to render food-taking very difficult. She was conscious, as practically all cases of tetanus are, throughout her illness.

Some years later I for the first time treated a case of acute tetanus with hypodermic injections of carbolic acid as advised by Baccelli, and increased the dosage to a large extent without inducing any symptoms of carbolic poisoning. The patient seemed to do well, and as day after day went by there arose a hope that the man might recover; a hope that was soon nipped in the bud by his death following a tremendous rise of temperature to 109° or thereabouts. Here again, as in the case previously mentioned, treatment *seemed* to be of value, while the result showed that in reality we were doing no good whatever.

The more chronic forms of tetanus are more favorable, of course, as are those in which the incubation period is long; but the question of the value of any given treatment is a most difficult one, as sometimes when dealing with a favorable case with fair prospects of recovery a sudden rise of temperature, accompanied by an overwhelming toxemia, will carry off the patient no matter what the treatment may be.

Very many drugs have been highly recommended for this disease, a fact which usually affords strong evidence that none is of much curative value. Some of these the writer has never used and therefore cannot discuss from a practical standpoint, while others have been given trial in a number of cases relatively large for a not common ailment. In looking over some of the records of the Pennsylvania Hospital it is interesting to note that there have been recoveries under various treatments. In some 32 cases admitted to the hospital since 1906 10 have recovered, a remarkably low mortality, but by no means a representative one. On the other hand one may see a number of cases occurring year after year in which all are fatal. Such indeed has been my own experience and I can recall but two cases of recovery in those under my care. The first recovery took place in a boy who had a well-marked case of tetanus, with the hopeful history of a long incubation stage of six weeks. In this instance I treated the boy with intraspinal injections of magnesium sulphate and was greatly pleased to note the immediate good results as shown by relaxation and sleep. After several injections at intervals of 48 hours or more recovery was complete. During the month following I treated three other cases of tetanus by the same method, in one case antitoxin being given subcutaneously in addition. All three of these cases died, and in one at least the magnesium sulphate injection showed a cumulative or a multiplied action and may have contributed in some degree to the patient's death.

A study of the ten cases which have recovered during the last five years at the Pennsylvania Hospital is interesting:

CASE I (815): This had an incubation stage of eleven days. Tetanus developed from a wound in the toe, and accordingly at the time of admission this member was amputated. The treatment consisted of hypodermic injections of carbolic acid (8 drops of a 2 per cent. solution every 4th hour, later on 15 drops of a 1 per cent. solution every 4th hour). No antitoxin given. Recovery.

CASE II (1453): Incubation stage three weeks. Antitetanic serum, 3000 units more or less frequently. Sodium bromide and chloral internally. Recovery.

CASE III (2334): Incubation stage eight days. Antitetanic serum 3000 units at intervals. Sodium bromide and chloral by mouth; carbolic acid 100 minims of a 1 per cent. solution at once and then 50 minims of a 2 per cent. solution hypodermically every 4th hour. Recovery.

CASE IV (3982): Incubation stage doubtful, possibly one day, but not likely. Treatment 6000 units of antitetanic serum, 4 minims of a 2 per cent. solution of carbolic acid every 4th hour by hypodermic method. Recovery.

CASE V (3697): Incubation stage 21 days. Treatment, antitetanic serum, 3000 units every 6th hour, hypodermically. Chloral and bromide by mouth. Recovery.

CASE VI (1047): Incubation stage about four weeks. Treatment, 60 c.c. antitetanic serum and then 30 c.c. and 15 c.c. daily. Sodium bromide and tincture of opium by mouth. Recovery.

CASE VII (1726): Incubation stage nearly six weeks. Treatment, magnesium sulphate by intra-

*Read before the Philadelphia County Medical Society, June 14, 1911.

spinal injection. No antitoxin. Sodium bromide by mouth. Recovery.

Case VIII (1761): Incubation stage cannot be computed. A child was born to the woman 17 days before admission. No history of a wound. Treatment intrauterine douches. No record of other treatment. Recovery.

Case IX (1960): Incubation stage cannot be judged. Large ulcer present beneath the tongue and other small ones in the mouth. Treatment, antitoxin 30 c.c. every 4th hour hypodermically. Sodium bromide and chloral by mouth. Recovery.

Case X (399): Incubation stage cannot be judged. No history of a wound could be obtained. Treatment, magnesium sulphate by intraspinal injection; Sodium bromide and chloral by mouth. No antitoxin. Recovery.

An analysis of these cases will show that four were treated with antitetanic serum alone; one with carbolic acid alone; two with carbolic acid and serum; two with magnesium sulphate alone, and one with no treatment at all excepting intrauterine douches. Several conclusions might be reached from this brief record: either that widely different treatments are effective, or that some cases will get well in spite of treatment, or even that treatment is of no avail. For many years I must say I had the latter opinion and have seen numerous cases die while none recovered until the first case in which I used the magnesium sulphate injections in 1907. I do not believe that magnesium sulphate is specifically *curative,* but it does afford the patient rest and sleep, and in so doing meets an urgent indication. Meltzer and Auer found that in monkeys intraspinal injections of magnesium sulphate retard the development of the symptoms and the fatal results, and this discovery seems to hold out a hope that if true also in human beings, antitoxin might be more useful if given more or less simultaneously with magnesium sulphate. The injection of magnesium sulphate should be given as follows: 1 c.c. of a sterile 25 per cent. solution should be given for every twenty pounds of body weight, but I feel sure that successive doses should be made smaller, as in at least one instance there was evidence of a much greater effect of second and third doses. The method is an attractive one, as in as short a time as 15 minutes after the salt reaches the spinal canal relaxation begins and in an hour is complete. The patient becomes somnolent or falls into a deep sleep, and in some instances becomes quite profoundly unconscious. The rest given the muscular and nervous systems must be of value in conserving the patient's strength, provided we do no harm in any other way.

The actual procedure is by no means easy and I remember two cases in which I was compelled to desist from attempts to enter the spine; in one because the attempted introduction of the needle without an anesthetic produced a tonic spasm which very nearly proved fatal, and in another because the administration of ethyl chloride preparatory to the operation caused a similar state. The introduction of the needle into the canal when opisthotonus is present is anything but easy, though it is possible,

The treatment by means of antitetanic serum has never come up to expectations excited by its usefulness in animal experimentation, particularly in its immunizing effect. The explanation apparently lies in the fact that the tetanus toxin has united so strongly with the nerve cells of the cord and brain, at the time that the disease has shown its symptoms, as to present an impossible situation for antitoxin to deal with. The antitoxin has been used hypodermically, has been introduced into the spinal canal by puncture and even into the ventricle of the brain, and the brain tissue itself, after trephining. The larger nerves of the extremity have been laid bare, and the antitoxin injected into the nerve itself, and into the sheath. The dosage of antitoxin should be very large at first, followed by lesser doses frequently repeated.

Bromides and chloral are probably more commonly used internally than any other drugs. Morphine and atropine are also used for their quieting effect. Chloretone has recently been recommended. Curare has been extolled by some writers for its paralyzing effect on the muscular structure of the body. Carbolic acid in my experience has not been very successful, though there is evidence which goes to show that it has value. Certainly if antitetanic serum cannot be obtained carbolic acid should be used.

In dealing with cases of such gravity as this disease always presents we should leave no stone unturned that might give the patient a little more chance in his battle with death, and yet the character of the disease itself should be taken into consideration, and no disturbing and painful measures should be taken which can be avoided.

To sum up as briefly as possible, a patient suffering from tetanus should be immediately given a large dose of antitoxin, say from 15,000 to 20,000 units American standard and about half the initial dose repeated every 6 to 12 hours as needed. The wound, if one exists, should be excised, cleansed with strong carbolic acid solution and subsequently dressed with a weaker solution. If the wound is situated in the finger or toe the member should be amputated, but it is not justifiable to amputate larger parts. Resection of suspected nerve paths is a logical procedure. Injections of magnesium sulphate may be given every few days as occasion arises and carbolic acid by hypodermic injection if thought advisable. Bromides and chloral may be prescribed, but unless used in very large doses are not very quieting in their effect. The nourishment should be given freely and the patient allowed to drink water frequently as the loss of fluid from sweating is very considerable. When feeding by mouth is impossible the nasal tube may be used or rectal alimentation begun. The patient should be kept in a quiet room, free from all noise and excitement.

In regard to the prophylactic treatment of tetanus there seems to be much evidence of the value of antitetanic serum as a preventive. It is difficult, of course, to form any opinion as to what wounds are in reality dangerous ones and what are not. Tetanus develops in many cases where wounds have been cleansed with antiseptic care and bound up with antiseptic dressings a short time after the wounds were received. It is not difficult, on the other hand, to say what wounds are in the majority as forming portals of infection of the tetanus bacillus; these are punctured wounds, particularly wounds from nails, wounds on the feet or hands acquired in or about stables, or where manure is present; Fourth of July wounds where powder and dirt are burnt into the hands or face. All such should undoubtedly be most carefully treated locally and an immunizing dose of antitoxin ad-

ministered, 1500 units being a minimum prophylactic dose. There does not appear to be sufficient evidence on practical grounds to conclude that either intraspinal or intracranial injections of antitetanic serum are called for. Theoretically also there is a question whether either of these procedures has any advantage over the subcutaneous method.

1624 Spruce Street.

THE STRENUOUS LIFE.

By I. L. NASCHER, M.D.,

NEW YORK.

SPECIAL LECTURER IN GERIATRICS, FORDHAM UNIVERSITY SCHOOL OF MEDICINE.

In a recent number of one of our New York dailies (*New York Times,* July 9, 1911), there is a lengthy article upon the early death of prominent individuals. It analyzes the cause of death of 591 persons, of whom the ages of 163 are not given and the death cause of 198 is unspecified. The article, while written in the popular language required for lay readers and lacking in scientific accuracy, furnishes the physician a subject for thought upon the extent and effect of the strenuous life. The article begins with the question, "Has the American reached the limit of his endurance?" An affirmative reply brings up several questions. Is the individual deteriorating mentally and physically? Is his mode of life tending to shorten his years? Are his mental and physical labors excessive? Are there unrecognized factors which shorten life? I believe an unqualified "yes" can be given in reply to each of these questions. While the duration of life has been lengthened through the better care of children and the better control of infectious diseases it has not been shown that more persons reach old age. Without statistics at hand to prove the assertion by figures it is a matter of common observation that we see comparatively few individuals of advanced years, while we see many who in the middle years, in the fifth and sixth decades, present the appearance and are subject to the ailments of old age.

I have previously ("Longevity and Rejuvenescence," *New York Medical Journal,* August 17, 1909), referred to the present day tendency to hasten the period of development and make a man of the growing child, pass over the period of maturity with indifference, and when the manifestations of decline appear, make frantic efforts toprolong the closing period of life. The tendency to hasten development is seen in our schools where the mental and physical labors imposed upon the child have about reached the limit of the capacity of the young organism. Compare the school curriculum of to-day with the curriculum of thirty or forty years ago. The child must learn all his parents did in their school days, all the advances in science made since then, and many subjects which were thought unnecessary in former days, yet the school age has not been lengthened nor the number of school hours increased. There is a limit to mental capacity as there is to physical capacity, and that the limit is often reached in school is evidenced by the brain fag which accounts for the inattention and irritability of the child during the later school hours. Class tasks are gauged by the capacity of the brightest minds of the class age, and the weaker minds must make excessive efforts to keep up with the leaders at their age who are already forced to extraordinary mental and physical exertion. From one-half to two-thirds of the child's waking hours are taken up with school work. This leaves insufficient time for recreation and violent athletics are taken up which are as injurious to the body as excessive studies are to the mind. The foundation of arteriosclerosis is laid in the schoolroom, of cardiac hypertrophy and high blood pressure on the athletic field. As a result of this hastened development and overdevelopment in our schools the city man starts out in mature life with mind and body impaired, with foci for senile degenerations awaiting the moment's irritation which would rouse the senile process into activity. The physician shares in the popular misconception that the limit of growth in stature is the limit of development. The brain is heaviest about the thirtieth year, the lungs have their maximum respiratory capacity about the same time, and the heart reaches its normal maximal size during the fourth decade. The period of development ends with the completion of growth of the vital organs, and this takes place between the thirtieth and thirty-fifth years. When, however, through excessive mental and physical labor the organs have reached the limit of their normal capacity before the time, we must expect that they will deteriorate earlier and senile changes set in sooner.

The country-bred youth is neither mentally nor physically the equal of the city-bred youth, who has been trained to the limit of his mental and physical capacity. He is not at his best until he has reached the limit of physiological development several years later than the city man, but from that time on he overhauls his city brother because he has developed slowly, lives slowly and ages slowly. The city-bred man ages more rapidly, not alone because he reaches maturity sooner, but because the strenuous life of the city favors earlier senile changes. He becomes aged before he becomes old. The man from the country coming to the city and taking up the rapid life of the city soon breaks down. He is not accustomed to late hours and insufficient sleep, restaurant food, overheated rooms and bad air, and the constant strain of exciting business. He does not age rapidly like the city man, the changes are not those of precocious senility, but those associated with clearly defined disease, generally beginning in neurasthenia. Even in pastoral districts the introduction of urban features has produced an unfavorable change in the mental and physical condition of the population. It has increased their wants and worries, and this is reflected in the increase of insanity among them. There can be no doubt about the deterioration of the race in civilized countries; the gradual diminution of the average stature of the French soldier during the past century, necessitating a gradual diminution of the minimum limit of size of the recruit, is evidence of this fact. The control of infectious diseases has been accomplished not through increasing the natural power of resistance, but through limiting the source of infection. The enormous increase in diseases of the heart, lungs, kidneys, and brain shows that the body is less able to stand the strain upon these organs. In this country the strenuous life which begins in the school causes an early weakening of the physical powers which is increased and hastened in the reaction following artificial stimulation.

Does the mode of life tend to shorten life? Notwithstanding the great advances made in sanitation, it has done little in improving the organism, either in its power to resist disease or in prolonging the span of life. Its great value is in the prevention of

disease, its effectiveness being directed to the etiological factor and not to the histological factor involved in disease. It can be shown that most of those who formerly reached advanced old age did so under unsanitary surroundings and in spite of the neglect of hygienic rules. They lived, however, quiet uneventful lives, had sufficient sleep and nutritious food, and were not subjected to the constant and intense strain of present day commercial and financial life.

Improper mode of living is undoubtedly the most important factor in causing early death among prominent persons of to-day. They do not sleep enough or at the proper time, they eat too much and improper food, they are irrational in their recreations. After five or six hours of intense mental strain the brain needs rest and brain rest means sleep. The German banker, broker, or merchant goes to the coffee house for an hour or two in the afternoon, takes a little nap, and is sufficiently refreshed to take up again his strenuous mental labors. The American, after five or six hours of intense mental concentration on exchange or in the office, with but a few minutes intermission for lunch, goes to the ball game or athletic event, substituting one form of excitement for another, or he goes to a meeting of business men and continues the mental strain of the day. He cannot spare an hour in the afternoon to give his brain rest, until neurasthenia sets in and he must spare weeks for his recovery. After the day's work an hour or two is spent at dinner and then comes the ball, the banquet, the theater, or another meeting with a midnight lunch followed by a few hours' sleep. Many men after the intense strain of the day seek diversion at the card table depending upon the brandy and soda and the strong cigars to supply the recuperation necessary to enable them to work. If we could follow the routine life of our prominent persons day after day for a week we would find that most of them have insufficient sleep and depend upon forced stimulation to keep them up.

It seems hardly necessary to dilate upon our national failing, improper food and improper feeding. In our hastily prepared and still more hastily eaten noonday lunches digestibility and food value are subordinate to taste. A small chop, the flavor of which is masked by the highly spiced dressing, a piece of lard-soaked pie, and a cup of coffee or a mug of ale, or perhaps the pie alone, is not the most wholesome meal even for lunch; yet this is one of the most popular of the noonday lunches. Dinner is usually taken at night, and is as a rule a heavy meal. Most men prominent in their vocations are also familiar with the banquet table, and within a couple of hours after they have had a hearty meal at home they are ready for a second meal at the banquet. Excessive drinking is not as marked as excessive eating and improper food, and alcoholism is rare, but gourmandizing seems to be a common failing among the great and nearly great, and many of them pay for it with their lives. Many of the deaths reported in the press as due to acute indigestion and those due to apoplexy during or following a heavy dinner occur in gourmands.

Improper recreation is another of the faults which tend to shorten life. In my paper on "Recreation as a Therapeutic and Hygienic Agent" (*Dietetic and Hygienic Gazette*, April, 1910). I formulated the rule that "recreation should be the antithesis of the work which necessitates it." Physical labor requires mental recreation, a sedentary occupation requires activity, etc. Chess does not relieve the brain fag of the writer nor is the play with a complicated plot the proper recreation for the man who has spent the day under mental stress in his office. To substitute one form of mental excitement for another is not recreation, however diverting it may be. Dancing may be a diversion, but it is no recreation to the tired mail carrier, and in like manner a pastime which demands mental effort is not a recreation to the mind. Other factors involved in the mode of life having a deleterious influence upon the organism are sexual excesses and perversions. Secret tippling is a common failing. A potent cause for nervous breakdown among those who have vast responsibilities is found in the secret obsessions and phobias, or fears founded upon threats. It is hardly necessary to refer to the many prominent men who have their body guards, house guards and private detectives.

Are mental and physical labors excessive? The fact that so many prominent persons break down and die in the prime of life from causes traceable to overwork or to excessive mental and physical strain is sufficient reply to that question. In the race for wealth and leadership men having less mentality or physical capacity than their competitors but equaling or surpassing them in ambition and energy, work to the limit of physical endurance and if still short of their mark further effort causes mental and physical breakdown. The work has been excessive. There are many positions involving responsibilities radiating in all directions and neither the mind nor the body can encompass them. Where the individual is already working under pressure a slight increase in the work will suffice to cause exhaustion. A school teacher who had a class of forty pupils received a class of fifty pupils and in a week she was suffering from neurasthenia. A typewriter working usually nine hours a day was obliged to work from twelve to fifteen hours a day for weeks and was then a physical wreck. A city official holding a position involving little actual work but occasional grave responsibilities was forced to face these responsibilities several times within one week and he was on the sick list for ten days afterwards. Such cases could be multiplied many fold. It simply shows that we are working under pressure and dangerously near the limit of human endurance.

Are there unrecognized factors that tend to shorten life? Anything which irritates the nervous system hastens its breakdown and shortens life. The vibration of motor vehicles certainly has such an effect upon the organism. We are becoming so accustomed to these vibrations that we no longer notice them unless the vehicle stops while the motor is still running. We then hear the rumble of the motor and feel the vibrations. When the vehicle is going these are masked by the noise of the running vehicle and the forward motion. Some persons complain of vertigo and present other symptoms of cerebral anemia after riding in such a vehicle and many persons complain of lassitude after the ride. A guard upon the elevated railroad found that if he stood all day upon the platform of the car containing the motor he became nervous, irritable and tired while he did not have these sensations if standing upon the platform of a car without a motor. The symptoms differ from the symptoms of sea-sickness and its allied disorder car-sickness, and there is a different cause, the latter being due

to unusual motion, the other to extremely rapid, fine vibrations affecting the entire organism. The effect upon the muscular structure is probably similar to the effect of the medical vibrators which stimulate the muscles, but if the stimulation is prolonged the reaction sets in in muscle exhaustion. I can only venture a guess at the pathological condition produced through the rapid and fine vibration of the organs, especially the brain. It is certain, however, that this motor vibration does irritate the nervous system and that the repeated iritation will produce a pathological condition which tends to shorten life.

Other factors referable to modern civilization and the strenuous life which irritate the nervous system and tend to produce disease, are the various forms of artificial light, some of which are painful to the eyes and produce actual mental distress, the express elevators of high buildings which produce momentary cerebral anemia, the wind pressure when riding in rapidly moving vehicles unprovided with wind shields; the telephone, requiring intense mental concentration to hear conversation and at the same time disregard other mental impressions of sight and hearing, etc. The American's ambition to go to the limit of physical ability, to reach the goal he has set for himself, has carried him to the limit of human endurance. He has already begun to deteriorate and degenerate, he is aged before he is old, he dies while apparently in the full vigor of his manhood. It needs no Daniel to translate the Mene, Mene, Tekel, Upharsin that is written in the death reports of our prominent men. It means today as it did in the days of Belshazzar "the strenuous life kills" though not by the sword of a Darius but by the slower but equally certain pathological processes of outraged nature.

631 East One Hundred and Sixty-eighth Street.

THE OPERATION FOR HYPOSPADIAS; ITS PRESENT STATUS.

By ERIC CARL BECK, M.D.,

NEW YORK.

ATTENDING SURGEON TO ST. MARK'S HOSPITAL, INSTRUCTOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, CHIEF SURGEON AT THE GERMAN POLIKLINIK, ETC.

There are still so many general practitioners who doubt and distrust the efficacy of this very simple procedure that it is time to proclaim again that the operation for hypospadias is a successful operation, and can be made use of in the greater majority of cases. I use the term "greater majority of cases" advisedly and shall return to it later on.

It is a fact that many boys are born hypospadiacs, grow into manhood, marry, and create offspring. As long as the vivacious motility of the spermatozöon is preserved fecundation is possible. We know that spermatozoa have been placed in the human vagina by artificial or mechanical means and impregnation has resulted therefrom. But these cases of hypospadiac fatherhood are rare, and many a poor sufferer has shunned the married state because he knew his own imperfection and feared the eventual loss of his wife's love with the advent of her knowledge of his sexual shortcomings.

It is needless to state that a fair percentage of our annual suicides consists of men afflicted with this unfortunate malformation. I distinctly recall to mind a young man who was engaged to be married to a very charming young lady, and who entreated us to restore him to the normal state, as his fiancée insisted upon being married on a certain day about three months after the time he first came to us for advice. His ultimatum to us was that he would drown himself if we didn't succeed in making a man of him.

His was the balanic type of hypospadias and we had very little to contend with in displacing his urethra forward. His only complaint was that during the next few months he was unable to hold his urine longer than four hours at a stretch, probably caused by the irritation of the catheter. We have noticed this incontinence of urine in many cases, but they all return to normal within three or four months after the removal of the catheter.

There is no knowledge without experiment, and for experimenting we must have cases. But the cases alone are not sufficient, we must have the master mind and the master hand to carry these experiments out rationally. When a number have been completed and the years have rolled by, then, and only then, are we justified in making the definite statement that such an operation or such a chemical compound is truly efficient.

When the dislocation of the urethra was first mentioned and the technique later published, no one doubted but that it was feasible. But what would be its limitations? I was still a student when one of the older men of the Post-Graduate Medical School and Hospital made the remark to Carl Beck, "Beck, beware of the incurvation."

It is with the idea and the hope of placing this operation of dislocation of the urethra in hypospadias in its proper place that I have written this article. There are three forms of hypospadias, differing simply in the location of the false opening of the urethra. The balanic, the most frequent, the penile, and the scrotal. I think the nomenclature fully describes the location of the false opening.

Where do we hope to find the greatest extensibility of the urethra? Surely we should familiarize ourselves with the qualities and properties of the body or organ we expect to operate upon. According to the table of measurements of the penis taken from Waldeyr's "Anatomy" the distensibility of the urethra varies in accordance with the size of the pars libera of the penis. Length of entire urethra: Long urethra of adult, 24 cm.; short, 14 cm.; medium, 18 to 20 cm. Length in new-born, 5 to 6 cm.; in child of 1 to 2 years, 6 to 7 cm.; in child of 5 years, 8 to 10 cm. Length at puberty, 10 to 12 cm. The pelvic and perineal portions are fixed, urethra fixa. The penile portion is movable, urethra mobilis. In this movable portion of the penis the urethra is entirely dependent upon the state of the penis dilating with erection and vice versa. Taking the average figures given by Waldeyr as measurements of the penis in its state of laxity and erection, viz., 9 cm. and 16 cm., we find that the urethra is distensible, in the adult, to the extent of 7 cm. or 2.775 inches.

From the measurements given in Waldeyr's "Anatomy" we may gain a pretty fair estimate of the distensibility of the urethra, that is, of the probable limit of stretching. It is not wise to elongate the urethra to its fullest extent, as it is then that the incurvation of the penis occurs; when the organ becomes erect. I think the fair medium is to make use of about 50 per cent. of the distensibility. This naturally points out the possible and impossible operative cures in hypospadias by the simple use of Carl Beck's dislocation procedure. For instance in the adult, where the extensibility of the urethra is

a little over two inches, all cases in which the false opening is located within one inch of the tip of the glans penis, are curable by this method. In children and youths we must figure our proportions accordingly. The ideal case for operation, then, is one of the balanic type. I shall consider this form of hypospadias in describing the operation, as it is the simplest one.

The patient should be placed in deep narcosis to assure thorough laxity of the organ, and prevent possible erection of the penis. The entire penis is sponged off with alcohol and then coated with tincture of iodine. Cotton gloves on the hands of the operator facilitate handling of the organ and prevent slipping. An assistant grasps the glans very firmly with two fingers and exerts moderate traction so that the false opening becomes as prominent and as large as possible. A thin rubber catheter is introduced to act as a guide while the process of dissection is going on. The catheter is easily felt by the operator through the very thin skin overlying it.

The incision is made parallel with and to one side of the urethra. We have made it a rule of late to incise to one side so as to create a small flap with which to lift the urethra up and out. Of course great care must be taken with this step, as it is the most delicate part of the operation, and the smallest puncture of the urethra means a fistula which may remain permanent. An assistant with a watchful eye and an ever-ready sponge is an absolute necessity. It is important to dissect out a sufficient length of urethra so as not to cause too much tension when the dislocation forward has taken place. About two inches is the average.

For creating the new channel in the glans we have made use of a bistouri which is turned to the right and left to make the opening in the glans sufficiently large. There is always some contraction there later on, and this must be thought of at the time of operation. Four thin silk sutures are run through the anterior opening of the urethra equally distant from one another. The ends are drawn through the new channel in the glans and using the silk threads as a handle, the urethra is pulled forward into its natural position. The sutures are rethreaded on a needle and the urethra is stitched to the circumference of the freshly created meatus. One of the ends may be left long and run through or around the catheter to keep it from sliding either in or out. The wound in the body of the penis is sewed up with fine catgut, a thin strip of sterile gauze placed over it, and the whole encased in an adhesive or collodion dressing.

The patient must be kept on large doses of potassium bromide and a bland diet to prevent erections, which will destroy the fruits of the operation. If nothing interferes with primary union the catheter may be removed after the fifth day and the stitches about the tenth.

I am sorry to say that three cases were failures on account of the unruliness of the patients, but of the last twelve cases of balanic hypospadias all were successfully operated upon.

In the penile type the tension placed upon the urethra has always caused incurvation, if not when lax, then at least when the penis was erect. One case of scrotal hypospadias, I remember, required two operations. The first one the dislocation of the urethra as far forward as possible, and the second the formation of Thiersch flaps. Another case of the scrotal type which had been operated upon came into my office the other day and showed a surprisingly good result. Good in so much that the boy, who is now nine years old, can urinate easily and comfortably, but his penis is extremely small. It is nothing more than a very small piece of pendulous tissue.

The most unpromising case for operation I have ever seen Dr. Carl Beck attempt to remedy was apparently one of hermaphrodism. The boy was five years old and showed but slightly developed genital organs, his scrotum being split into two halves, simulating the labia of a large girl. His penis was but elementary. It looked like a clitoris, especially so when his thighs were brought in contact. When he urinated the urine was sprayed out of a funnel-shaped opening at the base of the penis. It was necessary for him to squat while urinating. The operation brought to light a scanty inch of urethra, and when his scrotum and penis had been repaired his genital organs looked like those of a boy about ten months old. We were surprised at the remarkable result two years after the operation.

For a detailed account of this case see the article by Beck. "On some technical difficulties in the distention method for hypospadias and other urethral affections," in the *New York Medical Journal* for August 14, 1909.

Comparing the results of these different cases—there are more than twenty that I can call to mind—and not only considering the satisfaction of the surgeon, but also bearing in mind the vital cause, the impulse that drives the sufferer to the surgeon for relief, I think it is fair to claim that the dislocation of the urethra is a positive cure in the balanic type, and in some cases of the penile form in which the false opening is not too far removed from the tip of the glans. Not enough time has elapsed to prove whether the urethra will adjust itself as the boys grow older, and the youngsters that I have seen operated upon as babies are still mostly under ten. Many of them drop out of sight completely, and if we see one at times in our clinics long after the operation we may count ourselves fortunate indeed. It is hard to draw up statistics of these cases, when one would like to cover a period of ten or fifteen years.

One thing more. Approximately 80 per cent. of the cases seen have been in children of Jewish faith. I have made it a rule to examine them carefully before operation, laying special stress upon how soon after birth they were circumcised. Within the last year I have seen four cases where the baby was but three or four weeks old. In each case the false opening was found at the border of the foreskin and a small indentation on the face of the glans seemed to point to a once patent normal urethral opening. Are not some of these cases artifacts? Are not, perhaps, many of them? Do not many of these poor babies become tuberculous on account of the ignorance of the circumcising official? This is a delicate subject to bring before the public, but there must be some way of checking this malpractice, or rather the criminal carelessness of the officiating person. Hypospadias in itself is such a terrible affliction; let us not increase the misery of these poor afflicted ones by permitting the continuance of this practice by surgically ignorant and inexperienced persons. Why should not the law compel all male children on whom circumcision is to be performed to be taken to a competent physician or surgeon for the operation?

REPORT OF A CASE OF CONGENITAL CAVERNOUS ANGIOMA OF THE NECK.

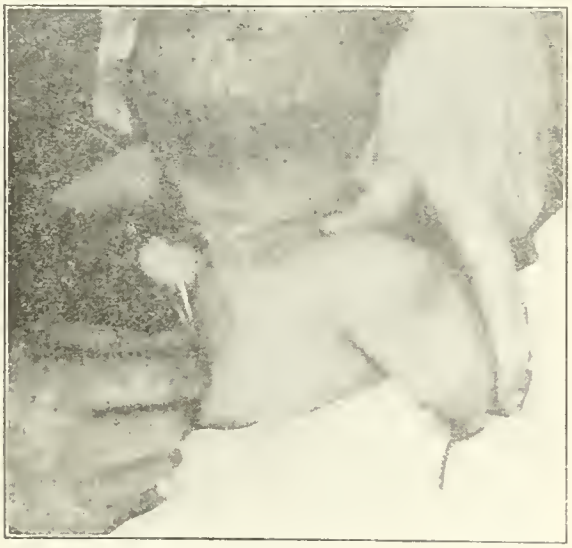
By ANDREW J. GILMOUR, Ph.B., M.D.,

NEW YORK.

The parents are both healthy. The patient is an only child. On December 30, 1909, one day after the birth of this infant, the midwife in attendance brought to the clinic a child well nourished, perfectly healthy, except for a tumor, which she had noticed at birth, on the back of the child's neck. The tumor was described as having at birth the color of the umbilical cord, but of the same size as at present.

Physical examination showed a tumor at the middle of the back of the neck at its junction with the shoulder. This tumor was situated just within the middle of the base line of a triangular area of a light red color representing a birthmark. The base, 3½ inches long, extended straight across the back of the neck just below the tumor. The apex of the triangle was slightly below the vertex, a distance of 3 inches at right angles to the base of this triangle. This light red area when last examined on October 27, 1910, was practically the same as when the patient first came under observation. The tumor itself was 1 inch in diameter, and on superficial examination appeared to be sessile. A more careful examination by raising the tumor showed it to be pedunculated. The pedicle was extremely short with a diameter about one-quarter that of the tumor itself. The color was a pinkish red with a few traces of purple. Pressure caused the disappearance of the contents of the tumor, leaving a thick boggy sac beneath the fingers.

Two days later the purplish color of the tumor was more distinct; at the end of the week the pinkish color had been etirely replaced so that the tumor was a dark purple. The tumor had slightly



increased in size since birth. At the end of three weeks, when last seen, the tumor remained practically the same size. The parents were to have brought the child later for operation, which they did not do.

The patient, having been lost track of, was visited on October 27, 1910, and was found to have had the tumor removed by a private physician when the baby was two and one-half months old. The removal had been complete; a distinct vertical scar remained over its former site. The child was healthy and robust. The mother said the tumor had gradually increased in size up to the time of the operation, but from her description it could have been but a trifle larger than when last seen.

The accompanying photograph was taken three days after birth.

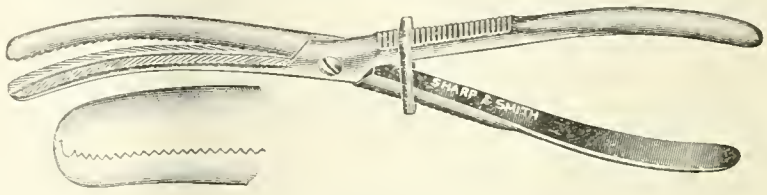
A NEW HYSTERECTOMY CLAMP.

By HOWARD CRUTCHER, M.D.,

ROSWELL, NEW MEXICO.

On February 29, 1896, the Medical Record published an article in which I presented to the profession a new and extremely simple lock, consisting of a steel ring sliding over serrated shanks, which up to that time had been applied only to clamps used in vaginal hysterectomy. Since that time



I have fitted the lock to other appliances, which have been reported from time to time in this journal.

In the present case I desire to illustrate my latest hysterectomy clamp, which differs radically in the blades from the older ones. The new clamp has long, wide, curved blades, one grooved, the other with a tongue to correspond. The screw has been made heavier. The idea of the improved blades was suggested to me by Mr. R. M. Hays, a medical student of Dexter, New Mexico, to whom my warmest thanks are due. In perfecting the blades Mr. Hays followed the general lines of the familiar hemorrhoidal clamp, modifying them to meet the special conditions found in the broad ligaments of the pelvis.

My reason for presenting the present clamp is that I have found the old ones, with short blades, undesirable in most cases, two or more of them being required at times on a single ligament. The ideal method consists in applying a single clamp on each side.

Antityphoid Vaccination by Way of the Intestine.—Jules Courmount and A. Rochaix have been studying for three years the possibility of causing autityphoid vaccination through introduction of typhoid material into the intestines. They give their conclusions from this work as applied to animals and man. Vaccination by introduction of toxins into the intestines is possible, but the material cannot be introduced by the mouth. It must be injected into the large intestine assisted by the use of laudanum in the fluid. These injections are well borne; after a negative phase immunity is established in the goat, rabbit, and guinea pig. Immunity is also antitoxic; the agglutinating, bactericidal, and bacteriolytic properties appear in the serum of the subject vaccinated. Man bears the injections well, with no bad effects. Agglutinating, bacteriolytic, and bactericidal powers are developed in human serum, and immunization like that from the cutaneous method is probable. This method is absolutely harmless and should be tested.—*La Presse Médicale.*

THE BRAND BATH IN TYPHOID FEVER.

IN the *Zeitschrift für diätetische und physikalische Therapie*, Bd. XV, 1911, Dr. Simon Baruch of New York compares the results of the Brand bath as shown by statistics of W. H. Thomson, W. Gilman Thompson, H. R. Loomis, Osler, and others with the results of milder cold water treatment advocated by Curschmann, who led the German doctors to his milder method and which has gained vogue in this country. In the St. Jakob's Hospital under Curschmann's supervision 1,229 cases of typhoid fever resulted in a mortality of 18 per cent., while the statistics of some American clinicians, also from civil hospitals, show a mortality of about 7 per cent., the number of cases being 1,268. The latter statistics are sustained also by Hare of the Brisbane hospital at Melbourne, whose mortality was 7.05 per cent. Baruch does not content himself with a mere statement of statistical results, but brings forward arguments opposing the views of the great Leipzig clinician, and deplores his influence upon the medical profession in this matter. Quoting from Nothnagel's "Pathologie und Therapie," Curschmann writes: "At first under the imposing influence of Brand and his followers and of the overestimation of the significance of high temperatures, cold baths as low as 6° C. were applied. Consequently it became necessary not rarely to use 10 to 15 baths in 24 hours. Most physicians have therefore returned to milder procedures." Dr. Baruch compares this statement of Brand's views with the latter's published statements. In his monograph "Die Hydrotherapie des Typhus" Brand writes "Not the reduction of temperature, but the stimulating action of water is the principal thing in typhoid fever. . . The chief indication is to meet the combined attack of the poisons upon the brain, the nervous system, the heart, and the abnormal blood conditions by a correspondingly sustaining method. . . Six baths in twenty-four hours is the largest number necessary." Moreover, Baruch says, "Brand never applied a bath of a temperature below 18° C., the usual temperature being 20° C.

Baruch then describes his own method as a gradual introduction to the cold bath, which is adapted to nearly every case of typhoid fever. When the rectal temperature is 102.5° F. or over, without local manifestations to account for it, he invariably has the patient wrapped in a sheet and blanket, placed in a rocking chair, and drawn to the bath room, where a tub filled with water at 90° F. awaits him. The patient is bathed and well rubbed for twelve minutes, dried, and returned to bed. If the rectal temperature is still above 102° in four hours and the patient is awake, a second friction bath for twelve minutes is administered at 85° F. This practice is repeated every four hours under the same conditions, the bath temperature being lowered each time five degrees until 70° F. is reached. If one of these baths reduces the rectal temperature two degrees or more during the first week Dr. Baruch claims that the diagnosis is negative; the more nearly the rectal temperature, taken fifteen minutes after the bath, approaches 102.5° the more probable is the diagnosis of typhoid fever. After the diagnosis is established the bath at 70° for fifteen minutes with active friction is given at the bedside, according to Brand, every four hours, when the patient is not normally asleep. When the reaction is not good or the patient's teeth chatter during or after the bath, the latter should be shortened, but the temperature should not be raised. A good reaction is the essential of every cold water procedure.

MALIGNANT CERVICAL LYMPHOMA.

PERHAPS no familiar clinical affection is so little understood, even by good practitioners, as extensive hyperplasia of the cervical lymphatics. Cornet was doubtless the first to show that the very worst and most characteristic cases of "scrofula" were often, if not commonly, nontuberculous in character. He coined the term "pyogenic scrofula" to characterize these cases, and attributed them to ordinary pyogenic cocci, taken up in the mouth, nose, throat, etc. He even went so far as to state that no abrupt line could be drawn between such cases and malignant lymphoma. There seemed to be no limit to their growth, and they could destroy life by compression or exhaustion, or both conjoined. Schleich was at much pains to discriminate between pyogenic and tuberculous cervical lymphomata. The latter were bound to become caseous, while the former never did, save in mixed infection. Many a child, horribly deformed by enlarged cervical lymphnodes, is going about to-day with the stigma of tuberculosis. It is confidently anticipated that the condition will progress and that the child is doomed to an early death. It often becomes necessary to extirpate these glands because of the pressure symptoms. Scores of these lymphomata, of the most varying dimensions, may be incised without the slighest evidence of caseation, and tubercle bacilli will not be found. There is no evidence of lymphomata in other localities, nor of any essential anemia or cachexia. Nevertheless new ganglia rapidly enlarge and the patient soon becomes worse off than before and is repeatedly operated upon until the case becomes inoperable. But these cases are by no means essentially malignant, for, as Schleich and Cornet state, spontaneous involution is often seen. Older authorities recognized a "scrofula fugax" which was of this type and doubt-

less nontuberculous. Much may also be accomplished by treatment, and in general it may be believed that only a small percentage of such cases end fatally, and that when this occurs we have a right to accuse something more serious than pyogenic scrofula.

As years have elapsed since the efforts of the authors quoted were published, it should be of interest to note what a recent writer has to say on the subject, and Ziegler should be worth quoting, although probably not representative of the clinicians. At a session of the Schlesische Gesellschaft für vaterlandische Kultur (*Deutsche medizinische Wochenschrift*, August 24), he discusses the frankly malignant forms of lymphoma. The chief problem to decide is whether we have to deal with a true neoplasm or an inflammatory granuloma. All evidence favors the latter view, and in this case a specific exciter should be necessary, similar to the cause of lues and tuberculosis. The predilection areas are the neck, axillæ, and mediastinum, which apparently argues for direct extension. Nevertheless he does not allude to pyogenic scrofula. Generalization occurs to other and internal structures, and while often deferred, is probably inevitable. Late complications may be numerous and varied. Bone lesions are mentioned, and this reminds us that Cornet always claimed that much "bone scrofula" was nontuberculous in character.

Ziegler lays much stress on prodromal exanthemas as showing the presence of a deep-seated infectious process. There is, therefore, a family resemblance between malignant lymphoma and mycosis fungoides. He intimates that Mikulicz's disease (tumor of the submaxillary and lacrymal glands) belongs to the same family. In splenomegaly we have another clinical type. As Köbner long ago showed, the primary lymphomata may sometimes be resolved by local injections of arsenic. It is to be regretted that Ziegler did not make some comment on the relations of pyogenic scrofula to malignant lymphoma. He does emphasize the fact that a disease which closely mimics tuberculosis of the lymphnodes has been abundantly shown to possess no element whatever of that affection.

MALINGERING AMONG CRIMINALS.

Not infrequently malingerers gain admission to the public wards of a hospital and become for a time a great source of worry to the internes as well as to the attending physicians. The usual presupposition that a person who has asked and gained admission to the hospital must be a sick man is very strong in the minds of hospital workers, and a malingerer enjoys "bed and board" for a long time, until finally the mind of the staff in regard to the absence of any disease in him is made up. And even when he is finally discharged with the diagnosis of malingering, the house physician experiences a curious uneasiness for a time lest something may have deceived him in the diagnosis, and the person discharged as a malingerer may be brought in seriously ill, following the very next ambulance call.

But malingering assumes no such serious proportions in a general hospital as it does in prisons, according to G. Frank Lydston, whose views on the subject are printed in the September issue of the *Journal of the American Institute of Criminal Law and Criminology*. In prisons the greater number of criminals answering a sick call are malingerers, and for a great many reasons. Some from a desire to escape work; others from a craving for sympathy and change from the deadly prison routine; others still from a liking for drugs, which was stilled by drink or by the regular use of various patent medicines when at liberty; many are really psychopaths and undergo various heroic treatments or even operations for the sake of these procedures only.

To a young prison physician malingering, it is seen, presents a very hard problem. He cannot but consider all applicants for treatment as genuinely sick, and must, therefore, spend a great deal of time in weeding out the "fakers." Chronic malingerers, too, persist in responding to the sick call, even though previous attempts have been punished by nauseating doses or the dark cell. Lydston was much bothered by such persons until he hit upon the simple plea of sounding the sick call at dinner time. The success of this move was astounding: one hundred and eighty men appeared on the sick list the day previous, only twelve were in line on the first day of the experiment! This success was repeated for the rest of Lydston's term of service; as his orderly tersely put it, they, meaning the prisoners, "couldn't stand the smell of the soup."

DROUGHT AND SANITATION.

That there is a correlation between drought and health conditions is a point too obvious to require any argument. In continued hot weather, especially in cities, the death rate goes up generally by leaps and bounds. The chief death toll is taken of young children. Infants in very large cities, when the temperature has been high and the sun scorching for weeks, die like flies, although this simile is not apropos, as flies flourish in hot weather. Heat of sun and air lasting for some time has a depressing effect on human beings of every age. This climatic extreme lowers the vitality of even adults so that it is a matter for no surprise that children suffer seriously. Extreme hot weather then *per se* is injurious to human life. The conditions it brings in its train are, however, more harmful still to health. The air of cities is then filled with dust and carries the germs of disease. Rain is the greatest cleanser of air and when rain is lacking the air of cities becomes foul and noxious. Food of every description is liable to become contaminated and more particularly milk, the food of children. A long drought is a season of trial to children in cities and the younger the children the more seriously are they affected.

The London *Times* of August 15 had a leading article on the subject of drought and health. It must be borne in mind that in England the people are not accustomed to long droughts and great heat. Thus when it is considered that in London a few weeks ago the temperature was 97° F. in the shade,

and in Greenwich more than 100° F. in the shade, it may be easily imagined that the children suffered terribly. There is little doubt that the low rate of mortality of infants in Great Britain is largely due to the more or less constant rainfall which keeps the air comparatively pure. The writer in the *Times* refers to the well-known fact that a hot and dry summer is usually attended or followed by a large infantile mortality, "a mortality presumably dependent partly upon the actually depressing effect of great heat upon children with no inherited tolerance of it and partly upon the accumulation in many places of waste matter ready to pass into active decomposition as soon as it is supplied with moisture." It is pointed out that after a prolonged drought there is often great difficulty in procuring adequate water supplies either for mankind or for animals and in the past there has been only too much experience of the consequences of the first flushing of the country by abundant rainfall. After all water is the main agent by which typhoid fever is spread and it is certain that in the event of sudden and heavy rains after drought an outbreak of typhoid fever is one of the consequences against which it is necessary to be on guard. Therefore sanitary authorities should not only watch carefully over the sources of water supply and over the channels whereby they may be polluted, but by educative measures protect consumers against errors of ignorance. Educative measures with regard to water-borne typhoid fever are surely urgently required in this country, where continued hot weather is of common occurrence and typhoid fever still unduly prevalent.

THE SURGICAL TREATMENT OF ANGIOSCLEROTIC GANGRENE.

Obliterating sclerosis of the leg arteries, depending upon the circulation of some toxic or infectious agent in the blood, leads in many cases to intermittent claudication, in others to progressive gangrene of the extremities. Amputation of the limb has been the final outcome of the many therapeutic measures used when the latter stage of the disease was reached. Several years ago Wieting of Constantinople conceived the bold measure of deflecting the stream of arterial blood from the narrowing arteries into the intact veins, thus obviating the necessity of amputation or at least limiting it in extent. In the *Deutsche Zeitschrift für Chirurgie*, Vol. 110, Nos. 4-6, 1911, Wieting communicates several new cases of the same character in which operation was performed by him or others and reviews the results obtained.

The unfavorable results and the consequently unfavorable comments of most surgeons Wieting explains by the failure of these surgeons to select proper cases for the operation. Not every patient with arteriosclerotic gangrene affords a favorable case, according to Wieting, for of the sixty patients observed by him he operated upon five only. Moreover, his technique is of the simplest, consisting of "intubating" the artery into the vein, or in anastomosing the two by means of lateral sutures, the vein being ligated centrally in either case. This method requires the least possible healing capacity from the artery, leaves any remaining arterial circulation intact, and in his experience has either obviated amputation altogether or limited its extent, or, finally, postponed it to a later and more favorable date.

The loss of a limb for any cause is a fearful calamity for a human being, and Wieting's communication deserves serious attention. We have not heard as yet of any attempts to follow his procedure in America, but the operative technique of American surgeons in the domain of vascular surgery is such that we may expect to see in the near future reports of Wieting's operation performed on this side of the Atlantic.

Bacteriology of Influenza.

It is known that at least three forms of bacteria seem able to cause clinical influenza. These are Pfeiffer's influenza bacillus, the pneumococcus, and certain diplobacilli described by Trumpp. The clinical varieties appear to bear no relation to the etiology. Thus typical epidemics of influenza of the most severe type have been set up by the pneumococcus, while in a mild sporadic case, a mere "cold," we may find Pfeiffer's bacillus. Hence it is extremely likely that other forms of microbes may set up what is clinically influenza; and not a few such have already been accused. In an article on grip in nursing infants (*Berliner klinische Wochenschrift*, September 4), Seligmann describes a germ which he terms the grip streptococcus. In an epidemic among nurslings none of the bacteria commonly accused of causing the disease was in evidence. It was noted, however, that in the so-called septic cases a peculiar streptococcus was discoverable in purulent collections in the living, and in the blood of the dead. This fact in itself might not seem significant, but it became apparent in time that the same germ was equally present in the nonseptic cases. The view first held that the germ in question represented a secondary infection was altered to one that recognized it as the primary and efficient cause. It was readily cultivated and proved highly pathogenic to mice and rabbits, behaving like the ordinary streptococcus. It is believed to exist in infants as a saprophyte, which may become pathogenic.

Photomicrographs in Natural Colors.

The subject of color photography is one which we have been hearing about for years. We read reports as to progress to date, yet despite the evident successful activity indicated, we seldom or never encounter any of the actual results in practical life. During 1910 and 1911 "autochromes" have been published in various periodicals, but chiefly if not solely in nonmedical journals. Doyen recently published such photomicrographs of the blood in the modest little journal entitled, *Je sais tout*. In a letter to the *Deutsche medizinische Wochenschrift* of September 7, Proell states that he has succeeded after great pains and expense in securing autochromic photomicrographs. He does not accompany his letter with samples, he says, because of the very great expense involved. The high cost, the great amount of time required, and the large number of failures in proportion to the number of successful plates secured seem to account for the present commercial insignificance of color photography.

News of the Week.

Health of the Canal Zone.—During the month of July, 1911, the total number of deaths from all causes among employees of the Isthmian Canal Commission was 56, giving an annual average per thousand of 14.06. During previous years the annual death rate for July has been as follows:

1904	6.24
1905	31.54
1906	64.71
1907	35.09
1908	14.68
1909	8.10
1910	11.80

Including both employees and civil population, the annual average death rate per 1,000 in the cities of Panama and Colon an dthe Canal Zone for the month of July of each year has been as follows:

1905	58.14
1906	67.72
1907	41.46
1908	29.11
1909	18.29
1910	22.48
1911	26.53

Computed according to race the death rate per thousand among white employees was 10.37, among colored employees, 10.27. Deaths from the principal diseases were as follows: Nephritis, 5; pneumonia, 10; hemoglobinuric fever, 1; malarial fever, estivoautumnal, 8; tuberculosis, 4; typhoid fever, 2. Thirty-nine cases of diphtheria were reported during the month, 20 from the Canal Zone, 15 from Panama, and 4 from Colon, with four deaths. One case of bubonic plague was taken from the S. S. *Guatemala* at the quarantine station, Culebra Island, on July 24, and the patent recovered. No cases of yellow fever, smallpox, or plague originated on the Isthmus during the month. The work of sanitation throughout the Canal Zone was carried on as usual during the month.

Charitable Gifts.—The Maine Medical School, which is the medical department of Bowdoin College, has received from Mr. and Mrs. Hugh Chisholm of New York the offer of a plot of land in Portland, together with $23,000 with which to erect thereon a dispensary building for the use of the school, provded the sum of $50,000 is raised as an endowment for the work. This will meet a long-felt want, and will greatly increase the facilities of medical education in Portland, and there is no doubt but that the required endowment will be forthcoming. The building will be known as the "Edward Mason Dispensary," in memory of Mrs. Chisholm's father.

The gift of $10,000 from Mr. James Patten toward the purchase of a building for the Frances Juvenile Home of Chicago is announced. The object of the home is the care of children with contagious diseases, and it is intended to supplement the work of the Cook County Hospital. The present capacity is fifteen, but it is hoped that it may soon be possible to increase this to two hundred.

By the will of the late Mrs. Annie T. White of New York, $200 each is left to the Skin and Cancer Hospital, the French Hospital, and St. Mark's Hospital in this city, and to the American Hospital in Paris, France.

Smallpox on Ship.—The Red Star line steamship *Vaderland*, which arrived in New York on September 25 from Antwerp, brought a case of smallpox among her 968 steerage passengers. The patient, a child, was removed to Swinburne Island, and the steamer was thoroughly disinfected before being allowed to land her passengers.

United States Humane Society.—Under this title an association has recently been ncorporated in New York, whose stated purpose is to prevent the loss of life wherever possible, and to prolong life wherever possible by means of inspiration. The organization also purposes to instruct the public in the best methods of rescuing all persons in danger on land or water through accident, neglect, or otherwise, and to furnish appliances for giving first aid to the injured.

Additions to Ray Brook.—The unveiling of two bronze tablets in the two new pavilions of the State Hospital for Incipient Tuberculosis at Ray Brook, N. Y., on September 26, marked the completion of an extension which doubles the capacity of the institution. The tablets commemorate the work of Dr. John H. Pryor of Buffalo and of the late Dr. Willis G. MacDonald of Albany, for whom the new wards are named. The hospital now has accommodations for about six hundred patients a year. The cost of the additions was $200.000 and the entire hospital property is valued at about $500,000, including 516 acres of farm and forest land. There are an administration building and four pavilions or wards, while an employees' building is under construction. The hospital reports cures in 76 to 84 per cent. of all incipient cases.

Public Health Lectures.—Dr. E. H. Porter, New York State Commissioner of Health, has announced the completion of a plan to give public health lectures under the joint auspices of his department and of the county and district medical societies of the State. These will include talks by a representative of the Health Department before the various county medical societies as well as public mass meetings. Lectures will be given on tuberculosis, typhoid fever, diphtheria, smallpox and vaccination, rabies, the value of vital statistics, carriers of disease, preventable diseases, the sanitation of a country home, sewage disposal, water filtration, etc. It is hoped thus to reach every corner of the State and to bring the Health Department and the members of the medical profession into closer relation.

The Chicago Medical Association is also planning a series of neighborhood health lectures to be given during the coming winter. The association expects to obtain permission to use the public schools of the city as lecture halls.

Harvey Society.—The first lecture of the Harvey Society for the present season will be given at the Academy of Medicine, New York, at 8.30 P. M. on Saturday, October 7, by Dr. Simon Flexner of the Rockefeller Institute for Medical Research, the subject of the lecture being "Local Specific Therapy of Infections." The second lecture will be given at the same place and time on October 14 by Prof. Albrecht Kossel of the University of Heidelberg, Germany, on "The Chemical Structure of the Cell."

Jefferson Medical College.—The new institute of anatomy, the gift to the college of Mr. Daniel Baugh, was dedicated on September 26. The institute, which is situated at the corner of Eleventh and Clinton streets, Philadelphia, was remodeled and equipped by Mr. Baugh, and will be known as the Daniel Baugh Institute of Anatomy of the Jefferson Medical College. Dr. Edward A. Spitzka,

professor of anatomy, is also the director of the institute.

Cholera in Italy.—During the week ending September 23, the official bulletin reports, there were in Italy 663 cases of cholera with 223 deaths.

Bubonic Rats.—Of 75,000 rats killed by order of the Department of Health of Seattle, Wash., in the last fifteen months, only one was found to be infected with bubonic plague.

Deaths of Centenarians.—Mrs. Mary McCarty of Stockbridge, Mass., died on September 23 at the age of 112 years, while Mrs. Nancy Coles, the oldest woman in Westchester County, New York, born in slavery in 1810, died on September 26, aged 101 years. Chief Satago, the past great sachem of the Chippewa Nation, died recently in Michigan at the age of 108 years.

Cholera in Tunis.—The outbreak of cholera in the Protectorate is reported, Tunis being particularly affected. About one hundred deaths a day are said to be due to the disease.

Dr. Sidney D. Wilgus has been appointed superintendent of the Eastern Hospital for the Insane at Kankakee, Ill., succeeding Dr. Frank P. Norbury.

Red Cross Seals for 1911.—The National Association for the Study and Prevention of Tuberculosis announces that the sale of the Red Cross Christmas seals will be continued this year as heretofore. A recent ruling of the post office department prohibits the use on mail matter of stamps or seals resembling postage stamps, but the design of the Red Cross seal has received the approval of the department and it does not come within the prohibitions so long as it is placed upon the backs of letters, etc. Fifty million of the seals have already been ordered for distribution.

Dr. Gregorio M. Guiteras of the United States Public Health and Marine-Hospital Service has been appointed official representative of the United States at the Pan-American Sanitary Conference, which is to be held in Santiago, Chile, on November 1 to 11, 1911.

College of Physicians and Surgeons.—The opening exercises of the College of Physicians and Surgeons, the Medical Department of Columbia University, New York, were held on September 28, President Butler of the University presiding. Dr. Edwin B. Cragin, professor of obstetrics and gynecology, delivered an address upon "Specialism in Medicine." The college opened with 329 students on the register, divided among the classes as follows: Fourth year, 87; third year, 96; second year, 64; first year, 81; special, 1.

$1,000 for Blood.—A young woman of Carlyle, Ill., recently received $1,000 as compensation for permitting a transfusion of blood from her arm to the veins of another woman. The recipient died in spite of the transfusion and the donor brought suit against her estate alleging that she had suffered injurious results from the operation and demanding $20,000. A compromise for one-twentieth of the sum sued for was, however, effected.

Removals.—Dr. Arnold Knapp to 10 East 54th street; Dr. Margaret A. Cleaves to 58 West 58th street; Dr. Abr. L. Wolbarst to 113 East 19th street.

Cholera Fugitives.—Nearly 400 steerage passengers on the French liner *La Savoie*, which arrived at Quarantine, New York, on September 30, were transferred to Hoffman Island for observation. It was said that they were all fugitives from the cholera districts along the Mediterranean who, to avoid detention, had skipped from Havre outside of the cholera zone.

Dr. S. S. Thorn of Toledo, Ohio, was the guest of honor recently at a banquet given by members of the Toledo Academy of Medicine to commemorate his eightieth anniversary.

Knox County (Ill.) Medical Society.—At the annual meeting held on September 21 the following officers were elected for the ensuing year: *President,* Dr. C. E. Beecher of Gilson; *Vice-President,* Dr. O. R. C. Bradley of Galesburg; *Secretary-Treasurer,* Dr. G. S. Bower of Galesburg.

Malden (Mass.) Medical Society.—The following officers were elected at a recent meeting: *President,* Dr. W. W. Lougee; *Vice-President,* Dr. W. W. Hartwell; *Secretary,* Dr. W. H. McBain; *Treasurer,* Dr. Louis F. McCarthy.

Colorado State Homeopathic Medical Society.—At the annual meeting in Denver on September 21 the following officers were elected: *President,* Dr. F. B. Swerdfeger, Denver; *Vice-Presidents,* Dr. J. W. Craig, Ault; Dr. Joel W. King, Golden; *Secretary,* Dr. C. M. Worth, Denver; *Treasurer,* Dr. E. B. Brown, Denver.

New York State Homeopathic Medical Society.—The forty-fifth semi-annual meeting of this society will be held in New York City on October 10 to 14, under the presidency of Dr. Orando S. Ritch of Brooklyn.

Council Bluffs (Ia.) Medical Society.—At the annual meeting held on September 18 the following officers were elected: *President,* Dr. H. E. O'Keefe; *Vice-President,* Dr. M. F. Warner; *Secretary,* Dr. D. H. Carson.

Canadian Journal of Medicine and Surgery.—The September number of this journal has, in addition to its usual scientific and medical contents, somewhat of artistic merits. It is embellished, it may be said, profusely embellished, by an excellent selection of half-tone illustrations, some reproduced from celebrated pictures representing epoch-making events in the history of medicine and surgery, others pictorially show beauty spots of the beautiful Canadian land, others exhibit the skill of Canadian engineers in overcoming the obstacles of nature, while yet others give one a good idea of some of the magnificent buildings of Ontario and Quebec devoted to science and education. The number is one of great interest from both a medical and an artistic standpoint.

Obituary Notes.—Dr. Robert E. Doran, superintendent of Long Island State Hospital, died on Saturday, September 23, at his residence, 102 Lincoln road, Flatbush, Brooklyn, N. Y., of septic endocarditis. Dr. Doran was born in Albany, December 26, 1870, and was graduated from the Albany Medical College in 1893. He was appointed to a position upon the staff of the Willard State Hospital for the Insane in 1895, and went through the grades up to and including first assistant physician. He retired from the State hospital to become assistant physician in the Craig Colony for Epileptics in 1901, and later returned to the Willard State Hospital. In 1910, standing first on the eligible list certified by the State Civil Service Commission, after a rigid examination, he was appointed medical inspector under the State Commission in Lunacy. Upon the retirement of the superintendent of the Long Island State Hospital in 1911, Dr. Doran was transferred to that position, in which he died, after a brief illness.

Dr. Henry T. Whiting of Rockford, Ill., a graduate of the Chicago Homeopathic Medical College in 1883, died suddenly at his home on September 13.

Dr. James H. Dickerson of Taylorville, Ill., a graduate of the Missouri Medical College, St. Louis, in 1899, and a member of the American Medical Association and of the Illinois State and Christian County Medical Societies, died at his home on September 15, aged 67 years.

Dr. Almon W. Hill of Concord, N. H., a graduate of the Boston University School of Medicine in 1887, died at the Homeopathic Hospital in Boston on September 17, aged 47 years.

Dr. Richard Hodgson of Stoneham, Mass., a graduate of the New York Homeopathic College and Flower Hospital in 1867, died at his home on September 14, aged 73 years.

Dr. William Alexander Graham of Durham, N. C., a graduate of the University of Pennsylvania Medical Department in the class of 1899, died suddenly at his home on September 19, aged 36 years.

Dr. Charles Edward Denhard of New York, a graduate of the New York University Medical College in 1874, a member of the New York State and County Medical Societies, the New York Academy of Medicine, the Obstetrical Society, and the Society of Medical Jurisprudence, and visiting physician to St. Mark's Hospital, died at his home on September 22, aged 71 years.

Dr. Eugene B. Sanborn, deputy health officer of the Port of New York from 1879 to 1908, a graduate of the College of Physicians and Surgeons, New York, in the class of 1867, died at his home in Machiasport, Me., on September 24, at the age of 79 years.

Dr. Charles E. Stammler of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1885, and a member of the Physicians' Mutual Aid Association, died at his home on September 27, aged 56 years.

Dr. Sophus A. E. Johnson of St. Louis, Mo., a graduate of the Chicago Homeopathic Medical College in 1893, died at his home on September 17, aged 54 years.

Dr. George William Reynolds of Chicago, Ill., a graduate of the University of Buffalo Medical Department in 1880, a member of the American Medical Association, of the Illinois State Society, and of the Cook County Medical Society, and attending surgeon to St. Joseph's Hospital, died at the hospital on September 19, of pneumonia, aged 58 years.

Dr. Edward Desmond of Spokane, Wash., a graduate of the medical department of Tulane University of New Orleans, Louisiana, in 1906, died at his home of typhoid fever on September 10, aged 41 years.

Dr. Ada Benton Morgan of Chicago, Ill., a graduate of the Hahnemann Medical College of Chicago in 1894, and a member of the American Institute of Homeopathy and the Illinois State and Chicago Homeopathic Medical Societies, died at her home on September 23, following an operation for appendicitis, aged 52 years.

Dr. John J. Cannan of Bradford, Pa., a graduate of the College of Physicians and Surgeons of Baltimore in 1892, and a member of the Pennsylvania State and McKean County Medical Societies, died at his home of pneumonia after a brief illness, on September 23, aged 43 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ST. ANDREWS UNIVERSITY QUINCENTENARY—REFORMS IN THE NAVAL MEDICAL DEPARTMENT—TUBERCULOSIS, POSTING CAMPAIGN, EXHIBITION, ROYAL COMMISSION, ATTACK ON DISPENSARIES—L. G. B. REPORT ON CONDENSED MILK—OBITUARY.

London, Sept. 15, 1911.

In the middle of September it is only natural for many of us to be looking forward to the opening of the medical schools which coincides with that of October. In the meantime, the University of St. Andrews, so closely connected with the profession, is celebrating its quincentenary during four days of this week. Representatives of learning from all countries have gathered in the ancient ecclesiastical capital of Scotland to do honor to the five hundredth anniversay of the university which has continued its academical career and importance through that long period. It is said that every residence within the old walls and for miles around is filled with delegates and guests. A memorial volume, "Votiva Tabella," gives an outline of the history of the university, describes the studies pursued, under the heading "The Inspirations of St. Andrews," and this is followed by a study of *belles lettres* by "ancient hands." The chancellor is Lord Balfour of Burleigh, who, with Lady Balfour, gave a brilliant opening reception on Tuesday to some two thousand delegates and guests in academic robes or uniforms. Sir J. Donaldson, the principal, took part in receiving them. The students gave a torchlight procession, in which they personated various characters and burned their torches at the close to the song of "Auld Lang Syne." On this day an interesting ceremony was the presentation to Mr. Andrew Carnegie of his portrait in oils subscribed for by the senatus and students in appreciation of his great services to this and the other Scottish universities. The portrait shows Mr. Carnegie seated and dressed in his robes as Lord Rector, the office which he said in his reply was the highest in his estimation he had ever held.

On Wednesday the chancellor received in the great celebration hall addresses from delegates of the chief seats of learning in the civilized world, and read a letter from the King regretting that he could not be present at the festival. A procession went to the cathedral, where Principal Stewart preached the sermon. After the service the students proceeded to the pier to welcome the Earl of Roseberry as their new Lord Rector. In the afternoon the chancellor delivered his address, in which he recounted the rise and progress of St. Andrews, the foundation of the university, and its history, its influence on education in many respects. In the evening a series of tableaux were given by some 140 artists, illustrating thirteen episodes in the history of St. Andrews.

Yesterday the Earl of Roseberry was installed with the ancient ceremony and delivered his address as Lord Rector. The felicity of Lord Roseberry's eloquence is proverbial, and can always be reckoned on. On this occasion, I learn from a telegram, that he appeared to surpass himself with an address full of charm and humor, in which he passed in review the five centuries in relation to Scotland and her oldest university, concluding with thanks to the students for electing him Lord Rector,

and appealing to them to continue the record worthily, for a nation which preserved its faith in God could never come to an ignoble end.

The other chief function of the day was the conferring of honorary degrees. Today, besides other excursions, there is to be one to the college at Dundee.

The medical officers of the Royal Navy have long had cause to complain of the indifference of the admiralty to the representations made on their behalf. Year after year the recommendations of the Durnford Commission have remained without effect. The continual postponement of all reform has had at least an effect which the lords of the admiralty no longer dare ignore—that is, the service has lost much of its attractiveness, so that candidates have been getting fewer and fewer until for some time now the medical service has been working below full strength. At last new orders, making a number of changes, have been issued, which it is hoped may prove real reforms as far as they go. In future the rate of pay will be increased at intervals of two instead of four years, which will give a slight aggregate advance during a number of consecutive years. Balancing this are alterations in "charge pay." It is estimated that the several changes will put naval medical officers on a par with their army brethren.

The Naval College at Greenwich is to be extended so as to include a medical department. This will work in connection with the Dreadnought postgraduate school, and that of tropical medicine. Naval surgeons, after four years' service, must before the end of their seventh year present themselves for examinations, having meantime gone through a six months' course at the college. Voluntary courses of three months for senior officers will also be held. At each home station facilities for studying bacteriology, *x*-rays, and other subjects, will also be provided, and reports on officers availing themselves of these facilities will be sent to headquarters, so that the director general will have a knowledge of their acquirements and promotion can only be conferred on his recommendation.

The examinations mentioned above will have more influence than heretofore; a surgeon who gets 75 per cent. of full marks will have a first-class certificate entitling him to a year's seniority, and 85 per cent. will give him eighteen months. A surgeon who fails after two attempts to get 50 per cent. will be retired, and that makes a difference in his gratuity on retirement.

The nursing service of the navy is to have a slight increase of pay, and an addition to its numbers and a reserve is to be established. An attempt is also to be made to provide a reserve of medical officers for service in the navy in a time of war.

The commander-in-chief must in the future refer the reports on officers of the department to one principal medical officer for his independent report. The medical officer of the senior flagship of a fleet is to be a member of the commander-in-chief's staff, and will advise on medical and sanitary matters, make reports to the admiralty and on all occasions have direct access to the commander-in-chief.

There still remain a few minor grievances, but I am informed that the concessions now made are regarded hopefully. Whether they will suffice to increase the popularity of the naval service is rather doubtful.

The unwieldly titles of inspector-general and deputy inspector-general of hospitals and fleets are abolished for the corresponding grades in the army service, viz., surgeon-general and deputy surgeon-general. One officer asks why not put it surgeon-admiral?

The special committee of the National Association for the Prevention of Consumption which appealed for help to carry out a great poster campaign, has now closed its accounts, which are in some respects satisfactory. The total receipts are estimated to be about £15,000. Of this sum £2,791-16-2 were from donations in cash. Coupon books were sold to the value of £132-14-3, and penny stamp collections realized £505-14. Then the gifts of posters and of posting spaces have to be added. A few more small sums may yet come in, and when the expenses incurred have all been defrayed it is intended to devote whatever balance may remain to the educational campaign against consumption.

A tuberculosis exhibition was opened at Reading on Monday and will close September 16. It was arranged by the Association for the Prevention of Consumption to show the great waste of life caused by the disease, how it is caused and spread, and the methods of cure and prevention. An opening address was delivered by Professor Sir Wm. Osler, who told the audience that much had been done in the last fifty years to arrest the ravages of tuberculosis in its manifold forms, the mortality having fallen by 40 per cent. One of the most effective causes of the reduction was improved housing and sanitation, but even yet too many persons were living under conditions inimical to health. Better food was another factor in the fight against disease. Tuberculosis could not be resisted unless the individual was in fighting form. This was specially the case with children. This because milk was so often the carrier of bacilli. He would make tuberculosis compulsorily notifiable and he advocated the establishment of special dispensaries in connection with all our general hospitals as a most effective method of combating consumption.

An appendix to the final report of the Royal Commission on Tuberculosis is issued this week in the form of a Blue-book. It contains an account of the investigations of the virus taken from cases of human tuberculosis, other than lupus, by Dr. Stanley Griffith. He gives the results of the examination of tubercle bacilli from 55 cases, from 54 of which cultures were isolated.

The anti-vivisectionists have been circulating a leaflet with the suggestive title, "Tuberculin Dispensaries: A Danger to Public Health." Of course it contains a hash of some of the misstatements that they have been in the habit of making.

A report of the Local Government Bureau on condensed milk gives the results of an inquiry conducted by Dr. F. J. H. Coutts. He has definitely shown that machine-skimmed milk is condensed to a considerable extent, and such a product is often used for feeding infants. It is obvious that infants fed with it are deprived of the fat necessary for their health and growth. Even when the milk is used with the full amount of cream sugar is added and this is not suitable for infant's food as the relation of the other elements of the sugar is altered. But the use of condensed skimmed milk implies a process of gradual starvation. Moreover, if the condensation process renders the milk bacteriologically pure, the liability to contamination as soon as the tin is opened is a constant danger, especially in warm weather. The result of such feeding is not only greater risk of acute disease, but prob-

ably an increased tendency to rickets. Dr. Coutts advises the labeling of all tins of condensed skimmed milk as unfit for the food of infants.

The death is announced of Dr. J. O'Gorman McDonogh, who served in the South African war as a civil surgeon and obtained the medal and clasp. He had been honorary surgeon to the French volunteer ambulance reserve for Greece in 1897. He took the licentiateship of the two Irish colleges in 1895. He had also been medical officer to the Royal Artillery at Aldershot. Of late years he had practised in London.

Progress of Medical Science.

Progress and Tendencies in the Practice of Medicine. O. H. Howe.
A Reminiscence of My Professional Life. D. W. Cheever.
Some Comments Upon the Results of Operative Measures for Knee Affections. H. W. Marshall and L. A. O. Goddu.
What Is a Tuberculosis Sanatorium? E. O. Otis.
A New Combination Mouth Gag and Tongue Depressor. R. A. Coffin.

Progress in the Practice of Medicine.—O. H. Howe reviews the progress made in the practice of medicine in the past twenty-five years. The telephone and automobile have improved the material surroundings of the physician by enabling him to cover larger fields of practice. The increased tendency to the employment of trained nurses; the greater enlightenment of the people; the advances in scientific medicine, as displayed by the modern treatment of diphtheria, tuberculosis, appendicitis, malaria, syphilis, and typhoid fever, and the introduction of surgical antisepsis, cocaine, and the *x*-rays are among the striking evidences of medical progress. The use of a greater number of alkaloids has added precision and facilitated administration. Some of the immediate problems and dangers of to-day are the following: Treatment is frequently neglected while the thought is centered in diagnosis. Another danger is lack of thoroughness. The physician should study methods of life and their effect upon health and longevity, so as to suggest proper exercises and diet as means of prophylaxis.

Reminiscences of a Professional Life.—D. W. Cheever comments upon his experiences of fifty years, comparing the practice of former years with that of to-day.

Operations Upon the Knee.—H. W. Marshall and L. A. O. Goddu state that there are some patients who undoubtedly require surgical interference before they can recover normal function of their knees, and these are individuals whose joints have become so injured by traumata or filled up with fat or chronic inflammatory tissues or organized exudates that the joint structures are unable of themselves to overcome the defect. Surgery then becomes an indispensable part of treatment, yet it should be emphasized that it is only one factor, although indispensable, in the cure of the disease. Upon the other hand, recovery is possible from quite severe and chronic lesions without operative interference, so that the matter of crucial importance as far as surgical interference is concerned is ascertaining whether the pathological state which exists does or does not exceed the limit from which restoration of function without opening the joint is possible. The ultimate conclusions regarding operative measures for synovial joint affections seem to be that they are often needed and that they are useful when they retard serious joint destruction, even though actual improvements in existing conditions do not occur, as well as when they restore perfect use of the joints; and, furthermore, results that should be expected most frequently after operations are partial restorations of joint functions rather than complete cures; also that the stage of the pathological process at which operative interference ought to be instituted practically is very difficult to judge and should be determined for each case individually with consideration to the normal physiological factors controlling the health of joints.

Tuberculosis Sanatorium.—By E. O. Otis. (See MEDICAL RECORD, September 30, 1911, page 698.)

Mouth Gag and Tongue Depressor.—R. A. Coffin has devised an instrument that consists of this combination.

New York Medical Journal.

September 23, 1911.

Experimental Poliomyelitis. M. Neustaedter and W. C. Thro.
A Study of Fifty Cases of Syphilis Treated with Salvarsan, with Special Reference to the Clinical Result and the Wassermann-Reaction. A. L. Wolbarst.
Report of Three Cases of Supravaginal Hysterectomy for Fibromyomata Uteri, with Illustration of a New Way of Applying the Tourniquet in Certain Special Cases. I. Collica.
Law, Medicine, and the State; Some Points of Contact. F. K. Hallock.
Railway Sanitation. C. P. Wertenbaker.
A Resumé of One Hundred Wassermann Tests. J. A. Roddy.
Sarcoma Arising from the Thymus Gland in an Adult; an Associatd Endothoracie Goiter. J. Funke.
Nasal Obstruction as Causative Factors in Bronchial Asthma Cases. J. Solow.
An Occipital Atlas and Atloaxis Dislocation. L. L. Thompson.

Poliomyelitis Propagated by Dust.—M. Neustaedter and W. C. Thro collected the dust of rooms wherein cases of poliomyelitis occurred and prepared extracts from these sweepings, which they injected into monkeys subcutaneously, intraspinally, and intracerebrally. The sweepings were obtained from cases of from six months' to three days' duration after the onset of the paralysis. The monkeys inoculated developed the flaccid paralyses typical of poliomyelitis, and at autopsy showed the pathological lesions of this disease.

Salvarsan.—A. L. Wolbarst concludes his report of experiences with the use of this remedy.

Supravaginal Hysterectomy.—I. Collica reports three cases in which supravaginal hysterectomy was performed. In one of these cases he devised a new method of applying the tourniquet for excessive hemorrhage. The tourniquet was applied on the tumor above the cut surface. In the first place this has the advantage that it can be always applied, as it is always possible to find a point on the tumor more or less near the surface of section where it can be set and turned. In the second place it allows the excision of as much of the uterine tissue as is wanted, which fact, in certain cases, is of advantage. In the third place it serves as a valuable means of holding and exercising traction on the tumor, thus greatly helping the operator. Finally, as regards its hemostatic action, though it is true that it does not control all the hemorrhage, as by the other method, still it stops a part, which is often the most severe, so as to allow the surgeon easily to control the rest by the common hemostatic means and quickly and successfully to terminate the operation.

Law, Medicine, and the State.—By F. K. Hallock. (See MEDICAL RECORD, July 22, 1911, page 200.)

Railway Sanitation.—C. P. Wertenbaker notes the fact that mosquitos, flies, and other insects are carried for long distances by trains. One of the most serious dangers is the scattering of excrementitious matter from the toilets of trains along the line of the road. The feather duster and "whisk" broom should be abolished, together with the common drinking cups. As regards the ventilation of cars, overheating and the presence of dust and smoke play a far more important part in the production of disease than does carbon dioxide.

Wassermann Tests.—J. A. Roddy emphasizes the feasibility of quantitative estimation of the Wassermann reaction. He states that by testing a fixed amount of patients' sera with several different amounts of complement, different degrees of complement fixation power can be recognized, the influence of medication can be more

accurately estimated than in any other way, and, in about 5 per cent. of cases, errors which are unavoidable in simple qualitative tests are precluded.

Sarcoma of the Thymus.—J. Funke reports a case of this condition occurring in an adult and associated with an endothoracic goiter.

Asthma and Nasal Obstruction.—J. Solow points out the etiological relationship between nasal obstruction and bronchial asthma.

Occipitoatlas and Atloaxis Dislocations.—L. L. Thompson reports a case of this condition occurring in a young girl who had been killed by hanging. It is stated that this is the sixth case in which similar pathological findings have been reported.

Journal of the American Medical Association.

The Experimental Method: Its Influence on the Teaching of Medicine. R. M. Pearce.
The Relation of the Intoxicating Dose of Horse Serum to the Protective Dose of Atropine in Anaphylaxis in the Guinea-Pig. H. T. Karsner and J. B. Nutt.
A Study of Fever in Tuberculosis with Reference to Its Causation and Treatment. F. M. Pottenger.
Experiments on the Relation of the Thyroid to Diet. R. Hunt.
A Plea for More Direct Methods in Dealing with Gastric Ulcers and Cancer. R. C. Coffey.
Smooth Atropby of the Tongue. L. S. Milne.
A Case of Brain Tumor. O. T. Manley.
Endemic Malta (Mediterranean) Fever in Texas. Further Notes on Its Distribution and Probable Source with Report of Additional Cases. Third Paper. E. R. Gentry and T. L. Ferenbaugh.
A Case of Sporotrichosis. R. C. Henderson.
Reportability of Syphilis and Gonorrhea. F. M. Greene.

The Experimental Method—R. M. Pearce condemns excessive dependence on the lecture system supplemented by extramural quizzes, though he does not believe in abolishing the didactic lecture altogether. Combined with demonstrations and laboratory work it is of great value in the proportion of about one hour of lecture to six or eight hours of actual laboratory or clinical work by the students.

The Protective Action of Atropine Against Anaphylaxis.—H. T. Karsner and J. B. Nutt have found that the minimum fatal dose of horse serum (0.2 c.c.) was insufficient to produce death when preceded by the administration of 0.001 gm. of atropine. In order to protect against 0.4 c.c. and 0.6 c.c. of horse serum, it was necessary to increase the dose of atropine to 0.002 gm. To protect against 0.8 c.c. serum, 0.007 gm. atropine was necessary, and against 1 c.c. serum, 0.02 gm. was needed. No dose sufficiently large to protect against 1.5 c.c. serum was possible, for before such a point was reached the animals succumbed to the dose of atropine. The presence of distinct symptoms of anaphylaxis in all those animals which were saved was sufficient evidence of the fact that they were highly sensitive. It was clear then that there was a quantitative relation between the protective dose of atropine and the intoxicating dose of horse serum.

Fever in Tuberculosis.—By F. M. Pottenger. (See MEDICAL RECORD, July 1, 1911, page 47.)

Relation of the Thyroid to Diet.—R. Hunt reports the results of his experiments which afforded additional support for the view that certain diets have specific effects on the thyroid glands of some of the lower animals. It is probable that analogous relations hold for human beings. Although it is possible that the effects differ in different classes of animals it would be interesting to determine if, in cases of hypothyroidism, the administration of oatmeal and liver, for example, would have a favorable influence, and if the withholding of them from patients with hyperthyroidism would be found advantageous. The most promising class of cases for such observations would be the mild degrees of thyroid derangement, such as those recently described by Kocher in his Nobel lecture.

Surgery of Gastric Ulcer—By R. C. Coffey. (See MEDICAL RECORD, July 1, 1911, page 52.)

Smooth Atrophy of the Tongue.—L. S. Milne presents a series of cases which would seem to show that smooth atrophy of the base of the tongue may occur occasionally in other conditions besides syphilis, as, for instance, in certain tuberculous cases and in association with general wasting states. In tuberculosis, for instance, out of twenty-five cases of smooth atrophy of the base of the tongue in which syphilis could not be definitely determined, seven were tuberculous. Only these seven, however, out of 196 tuberculous cases in the same series of 505 autopsies showed the condition. Of all the disease processes which lead up to the production of smooth atrophy of the base of the tongue syphilis is much the most frequent. In such proportions as in the present series, in which it existed in fourteen out of thirty-six syphilitic cases, the association was significant and at least a guide in clinical diagnosis.

Brain Tumor.—O. T. Manley reports a case of infiltrating glioma of the brain with calcareous deposits and cystic and degenerative changes.

Malta Fever in Texas.—E. R. Gentry and T. L. Ferenbaugh conclude that Malta fever is endemic throughout the older goat-raising sections of Texas. Although typhoid fever is prevalent throughout these sections, the authors believe that careful serum tests will show that a large proportion of the cases diagnosed as atypical typhoid fever will be found to be suffering from infection with the *M. melitensis*. All cases of Malta fever found have occurred in territory devoted to goat-raising and all patients either gave a history of drinking unboiled goat's milk or were actively connected with the goat-raising industry. While the authors have not yet found the *M. melitensis* in the milk of goats, the positive serum test obtained in 43 per cent. of goats examined pointed strongly to this animal as the source of infection.

Sporotrichosis.—R. C. Henderson reports a case of this condition, in which the lesion appeared as a ragged, depressed ulcer 1½ inches in length by 1 inch in breadth. Extending upward from this, along the back of the forearm toward the ulnar side, and passing around the elbow to the inner and under surface of the arm and thence up to the axilla, the lymphatic vessels were purple and distended, and eighteen or twenty nodules were present along their course. The vessels were filled with a dark serous fluid, and tension compelled the author to make some ten or twelve incisions for drainage. Later they discharged considerable pus. At no time was there pain or rise of temperature. The usual surgical treatment was employed, with potassium iodide internally. The patient made a slow but uninterrupted recovery.

Reportability of Venereal Diseases.—F. M. Greene refers to the action taken by the California Board of Health in declaring syphilis and gonorrhea reportable diseases as the most important step in relation to this subject as yet taken in this country. The author reviews the European legislation on the subject and describes the results as remarkable where—as in the Scandinavian countries—the measures have been so strictly enforced as to warrant control of every case. She defines the relation between the physician and society as widely different from that of twenty years ago, and urges that the public should be educated to realize the danger of venereal diseases. Where these diseases are reported both physician and patients are placed in a position of joint responsibility as regards the public health. Quackery in venereal diseases should be considered a criminal offense and laws should be made which should eliminate this social disgrace. The position of the medical profession in this relation should be on the side of the law. The attempted control has now been proved a failure in the principal countries of Europe, and the author believes that this fact should emphasize the advisability of placing venereal diseases among the other infectious diseases.

Phthisis in Wales. H. R. Jones.
Notes on the Clinical Appearance in Two Cases of Cerebral Disease, One Being Grave Organic Disease and the Other Purely Functional. J. H. Aytoun.

Vital Statistics of Ireland.—Sir W. J. Thompson presents a review of the vital statistcs of Ireland since 1864, and summarizes as follows: Emigration has enormously decreased; the birth-rate, notwithstanding emigration and a decreasing population, has remained almost stationary; the marriage-rate has increased of late years, and the death-rate, after many fluctuations, is decreasing.

Treatment of Constipation.—Sir J. Sawyer states that drugs should not be prescribed for this condition until dietetic and other measures have failed. In costiveness the therapeutic clues arise well from an old definition of it—namely, "in constipation the feces are hard, and may be retained from that cause, from weakness of the muscular coat of the large intestine, or from diseases of the anus, making defecation difficult or painful." Habitual constipation is a penalty of imperfect civilization. It is due to habitual abstinence from emptying the rectum whenever the natural impulse thereunto, the physiological call for defecation, is felt; it is due to habitual attempts at defecation when seated upon the usual seat, 18 inches high; it is due to habitually diminished activity of the psoæ and iliaci, of the respiratory muscles, and of the muscular fibers of the large intestines, and to rectal paresis from rectal distension; it is due to habitual abstinence from fruits and other vegetable foods rich in cellulose. It is due in some women to habitual diminution of beverages, from the design of minimizing urination. It is also due to insufficient mastication of food, especially of meat.

Poliomyelitis in an Adult.—C. M. Hinds Howell and B. T. Parsons-Smith report a fatal case of acute poliomyelitis occurring in a male aged 22 years. Pathological evidence showed that the case was a very severe and widespread one. The clinical evidence during life was not so conclusive, the first diagnosis which was offered tentatively being that of Landry's paralysis, the chief reason for this diagnosis being the ascending nature of the paralysis, the patient's age, and the absence of sphincter involvement. In cases of acute paralysis of this kind there are four possible conditions to consider: acute poliomyelitis, Landry's paralysis, acute toxic polyneuritis, and acute ascending myelitis. The last is probably the easiest to recognize with certainty owing to the fact that there is most pronounced sensory loss which ascends *pari passu* with the paralysis, and that the sphincters are early affected.

Pollen Vaccine in Hay Fever.—J. Freeman refers to Dunbar's ophthalmo-reaction as a diagnostic test for that susceptibility to pollen which constitutes hay fever, and describes Noon's method of immunizing hay fever patients by means of hypodermic inoculations of pollen vaccine. The cases treated in this way showed improvement of several forms: a greater freedom from attack, which, when it occurred, was less severe and of shorter duration than in former years, and which was accompanied by less constitutional disturbance.

Injuries to the Elbow Joint.—R. Lane Joynt states that a great many of these are cases of supracondylar fracture with displacement backward of the bones of the forearm together with the small lower portion of the humerus. Simple dislocation of both bones backward is a very rare injury in children. Fracture of the coronoid process of the ulna is an extremely rare condition. Frequently, in simple dislocation backward of both ulna and radius, bony growths occur in the brachialis anticus muscle. This is a myositis ossificans.

Traumatic Rupture of Abdominal Viscera.—A Rendle Short in a report of thirty cases of this condition makes the following observations: In every case of rupture of any abdominal viscus in which the pulse-rate on admission exceeded 100 the patient died within twenty-four hours. The temperature seems to be of more value. In five out of nine cases it was subnormal. Pallor or anxious expression is often remarked upon. Abdominal pain and rigidity are almost constant. Vomiting is not usual. The report further illustrates the deadly nature of injury to the spleen, on account of the frequency with which it passes unrecognized. Both the cases recorded were, when first seen, apparently little the worse for their hurt, though about six hours later both were in a dying condition. All cases of unexpected or possibly severe blows on the abdomen must be watched for several hours, however good the pulse may be, before they can be regarded as safe. There is an excellent series of recoveries after ruptures of the intestine, and there are several after severe injuries of the kidney, but only one here and there is saved after other abdominal injuries. Those who survive the immediate trouble seem to do well afterwards.

Chronic Obstruction of the Bowel.—A. L. E. F. Coleman and H. D. Everington report the case of a hydrocephalic imbecile in whom intestinal obstruction was caused by fecal impaction of an enormously dilated sigmoid flexure and rectum. The length of this loop of intestine was 45 inches and its greatest circumference 23 inches. It was found to contain nearly three and one-half gallons of feces.

Retroversion and Prolapse of Uterus.—A. E. Morison describes his method of operating for the cure of these conditions. The essential features of this method include, besides a preliminary perineorrhaphy by means of the Lawson-Tait flap-splitting operation, the following: The round ligaments are caught in the forceps, passed through the broad ligaments, and drawn through the latter until their loops meet behind the uterus. A strong silk suture is passed through them, including the back of the uterus, and is tied. In severe cases of prolapse a second suture is inserted in the same way an inch lower down to obtain a broader sling from which the uterus hangs. The position of the uterus is now entirely changed. It is raised high up in the pelvis, anteverted, and lying on the bladder. The broad ligaments are tightened up by the passage of the round ligaments through them; the uterosacral ligaments are also drawn upward, and both anterior and posterior vaginal walls are tightened.

Phthisis in Wales.—H. R. Jones states that coincidently with the fall in the death-rate from phthisis in England and Wales, the age of maximum mortality from phthisis has been postponed both in males and in females. In 1851-60 the maximum male mortality occurred between the ages of 20 and 25 years; in 1861-70, between the ages of 35 and 45 years; and in 1891-1900, between the ages of 45 and 55 years. The maximum mortality among females in 1861-90 was between the ages of 25 and 35 years, and in 1891-1900 between the ages of 35 and 45 years.

Two Cases of Cerebral Disease.—J. H. Aytoun describes two cases, one of cerebral hemorrhage and the other of major hysteria, both of which had an identical onset, with unconsciousness following an attack of retching. In both cases the teeth were tightly clenched and the conjunctival reflex was present. Only the later course of

the disease in the two cases made it possible to form a correct diagnosis. The point is made that a purely functional disease of the brain may bear a strong resemblance to a case of grave organic disease of that organ.

External Polypoid Tumors of the Stomach. J. Sherren.
The Management of Epidemic Summer Diarrhea and Vomiting, Including the Use of Saline Injections. H. K. Waller and G. Walker.
Remarks on a Case of Pleural Tuberculosis with Large Effusion. F. C. Carter.
The Detection of Tubercle Bacilli in Sputum. F. W. Eurich.
The Nutritive Value of Flours. M. Flack and L. Hill.
A Case of Septic Pneumonia Caused by a Hatpin. L. C. V. Hardwicke.

External Polypoid Tumors of the Stomach.—J. Sherren reports a case belonging to this group and states that these growths usually originate from the posterior surface near the greater curvature and grow into and become intimately adherent to the lesser peritoneal sac. These tumors are found more often in women and most frequently between the ages of 35 and 55. While occasionally the presence of an abdominal swelling is the only thing noticed, in other cases there is in addition a certain amount of abdominal discomfort. The tumors are mesoblastic in origin, are usually malignant, but in some cases are myomata and may present no sign of malignancy. All are liable to myxomatous change which may lead to cystic formation. Diagnosis of the exact nature of these tumors is impossible before operation.

Epidemic Summer Diarrhea.—H. K. Waller and G. Walker detail the treatment of this condition as carried out at the East London Hospital as follows: On admission the stomach and rectum are washed out with warm saline. For shock or collapse a mustard bath or pack is used. The child is then given a subcutaneous infusion of normal saline, or of a 5 per cent. solution of glucose in normal saline. The amount usually ordered is 7 oz. and this takes two hours to run in. The method of feeding is of the greatest difficulty. Water, preferably hot, is all that is allowed for twenty-four hours. The subcutaneous infusion is frequently repeated. Whey is valuable as the first food. Still better is a mixture of glucose and lactalbumin. Milk, freely diluted with water and with the addition of sodium citrate, is tried only when the diarrhea has shown signs of subsiding. Of drugs, calomel, castor oil, and opium seem the best.

Pleural Tuberculosis.—E. C. Carter reports a case of this condition in which the amount of fluid withdrawn from one pleural cavity at one tapping was 9½ pints. At autopsy performed six months later the whole of the right pleura, both parietal and visceral, was found to be converted into a stiff membrane of almost cartilaginous consistence.

Detection of Tubercle Bacilli in Sputum.—F. W. Eurich describes Koslow's modification of the "antiformin" method of examining sputum for tubercle bacilli, which modification obviates the use of a centrifuge and of a special fixation of the sediment on a slide.

Nutritive Valve of Flours.—M. Flack and L. Hill present tables which show the striking deficiency of white flour. The authors find that contrary to their previously reported results "standard" flour is better than wholemeal.

Septic Pneumonia Caused by a Hatpin.—L. C. V. Hardwicke reports the case of a man who died from a right sided septic pneumonia caused by the broken end, four inches long, of a hatpin with which he had been stabbed in the left side. The pin had traveled through the intercostal tissues and parietal pleura, just missing the left lung; though the diaphragmatic pleura, the diaphragm, the spleen, the stomach, the Spigelian lobe of the liver and finally the right lobe of the liver, where it was found projecting into the lower lobe of the right lung.

Berliner klinische Wochenschrift.

September 18, 1911.

Antagonism of Disease.—Soegaard, in an article ostensibly devoted to the antagonism which appears to exist between leprosy and cancer, cites other instances of reciprocal immunity, real or alleged. It was once claimed that an antagonism existed between cancer and tuberculosis, but accumulation of data shows that this is not present to the degree formerly assumed. Cancer patients show evidences of past tuberculosis at autopsy in 20 per cent. of cases—about half the incidence in noncancerous cases. Tuberculous cadavers show cancer in over 4 per cent.; nontuberculous cadavers in over 11 per cent. It has been shown with certainty that an antagonism exists between syphilis and cancer. Of the 325 cases of cancerous women, but one was syphilitic. Prostitutes and others who show a high percentage of spyhilis seldom die of cancer. Cancer is very rare in districts where malaria is endemic. The well known antagonism between cancer and erysipelas has been utilized therapeutically in Coley's fluid. It is asserted that erysipelas seldom develops in cancerous patients. What is true of erysipelas in this connection may possibly hold good for sepsis and pyemia. A very large percentage of cancer patients never suffered from the acute infectious diseases of childhood, and in a goodly percentage there was no history of any acute infectious disease at any period of life. Coming to leprosy it is known that no immunity exists to tuberculosis and it has commonly been taught that the former so predisposes to the latter that nearly all leprosy cadavers show recent tuberculosis. The author states that, while 20 per cent. or more die directly from tuberculosis, very many more die with tuberculosis, but not from it. Lepers are often attacked by septic processes, while erysipelas is strikingly prevalent. Cancer, on the other hand, is very rare in lepers. There seems to be a general law in virtue of which tissues which are readily attacked by infectious diseases, both acute and chronic, differ in some way from tissues most prone to neoplastic development, so that an antagonism exists between the two disease groups in the individual organism.

Two Cases of Tumor of the Spermatic Cord.—Schlueter recapitulates our knowledge of these affections to date as follows: Ninety cases were on record up to 1909. This small number stands in marked contrast with the frequent incidence of genital tumors elsewhere. The causes are naturally obscure, but traumatism plays a notable rôle. The tumor most commonly encountered is lipoma. Next in frequency are sarcomata. Mixed tumors, fibroids, and myomata occur to a small extent, while but one case of cancer is on record. During the past year or two three more cases of lipoma have been placed on record, not including the author's cases. The latter were both examples of lipoma.

The Larynx in Paralysis Agitans.—Graeffner has notes of 80 cases of this affection, of which 56 occurred in males. The patients were examined several times each with the laryngoscope with the following results: Forty per cent. showed no tremor of the vocal cords. In 21 cases (26.25 per cent.) there was tremor which was synchronous with the general tremor, while 27 patients exhibited a tremor of the cords which was not synchronous with the latter. These figures do not differ notably from those obtained by others with large material. A synchronous tremor of the cords is not an integral feature of the disease. All phases of action of the cords—adduction, abduction, etc.—were represented.

Münchener medizinische Wochenschrift.

September 12, 1911.

Paroxysmal Tachycardia.—Hering sums up an exhaustive analysis of this condition as follows: In regard

to the seat of irritation this may be atrioventricular or auricular. The former is certainly heterotopic; and probably the latter as well. Heterotopic paroxysmal tachycardia is probably due to a heterotopic original irritation. So-called nervous paroxysmal tachycardia may be of such origin solely. That tachycardia may be purely neurogenic appears to be shown by experiment. The extrasystole seems due to an irritant of heterotopic origin.

Diagnostic Significance of Psychogenous Lability of the Blood-Pressure.—Schrump and Zabel conclude from their investigations that great lability of systolic pressure within a short interval, called forth by psychic processes in the sense of desire or repugnance, speaks for abnormal excitability, *i.e.* nervousness. If with such lability of systolic pressure the diastolic pressure is approximately constant the vascular system is normal. But if the diastolic pressure shows variation to the amount of 15 per cent. of the systolic values, there exists a rigidity of the arteriocapillary system. It is possible therefore to distinguish between arteriosclerosis and psychogenous elevation of blood-pressure.

Normal and Premature Satiety.—Neisser and Bräuning state that a syndrome occurs in which there is premature satiation at meals. Constriction and improper (hasty, irregular) eating may be present as causal factors. This satiation leads to rapid loss of weight, but the prognosis is good. Normal satiety occurs at an intragastral water pressure of 16 to 18 c.cm. water. This pressure is due to peristaltic contractions of the stomach and to the mass of food. Peristaltic contraction of the stomach is due reflexly to the act of swallowing, and when the stomach sound is introduced the sense of satiety is delayed. Constriction of the stomach increases the intragastric pressure and incidentally produces premature satiety. This object has hitherto received but little attention and deserves further investigation.

Deutsche medizinische Wochenschrift.

September 7, 1911.

Von Pirquet's Reaction and Tuberculin Therapy in Surgical Tuberculosis.—Wilms states that in the fungous forms the reaction is negative, this arguing favorably, although in certain abscesses and fistulas it merely signifies that patients have become cachectic. Tuberculosis therapy is not essential for cases showing a strongly positive reaction. With weak or negative reaction it is a strong assistant to natural resources. A combination of tuberculin, *x*-rays, and general hygienic resources is the best treatment for surgical tuberculosis. The author looks forward to the day when conservative measures will supersede active intervention. The idea that foci must be extirpated or destroyed in order to prevent generalization he does not believe to be sound. Conservative measures raise the resistance and thus accomplish the same results; and without these measures surgical intervention cannot guarantee against extension. Extirpation of defensive organs like the lymphnodes can hardly be a sound resource.

Disintoxicating Action of Fresh Serum.—Dold continues his study of the action of fresh serum on toxic organic extracts. Not all fresh sera can paralyze the latter. In most cases the sera must be of homologous source. Kaolin absorbs the toxins of the organic extracts. Fresh serum when passed through porcelain filters no longer acts on the toxic extracts. The disintoxicating action is probably that of an antiferment. Attempts at immunizing by the use of homologous organ toxins have failed. The animals died of progressive intoxication. Toxins may be obtained from organs by simple immersion in saline solution for two hours. The organs need only to be incised.

Salvarsan Controlled by Lumbar Puncture in Metasyphilitic Affections.—Assmann states that in incipient paresis a six weeks' observation period showed no evidence of benefit either in the symptoms, lumbar puncture findings, or Wassermann reaction. In tabes in certain cases only there were both clinical improvement and favorable alterations in the cerebrospinal fluid. The Wassermann reaction was never influenced favorably. In cerebrospinal syphilis, on the other hand, constant uniform improvement was noted in all directions.

Magnesium Superoxide in Diabetes.—Hirose of Tokio has tested the truth of the claim that $Mg(OH)_2$ is able to reduce the amount of sugar in diabetic urine. The assertion was based of course upon a supposed oxidative property, and similar claims have been made for oxidizing agents, including oxygen inhalations. The author finds that any benefit derived must be very slight.

Treatment of Diphtheria.—Hoesch believes in the earliest possible injection of antitoxin. He gives from 1,000 to 2,000 units in mild cases, 3,000 to 4,000 in medium and severe cases. He has given high doses in all forms of the disease, either as a high single dose or by repeating the ordinary initial dose, but has renounced this practice since the size of the dose does not affect the course of the disease, *i.e.* does not make it clinically milder. Results obtained by experiment, in which adrenalin is made to antagonize the tendency to heart failure, are not in evidence at the bedside. In certain cases the patient is doomed in advance, and nothing can arrest the disease. A very large material is tabulated. Before the introduction of antitoxin about 37 per cent. of all cases ended fatally and of operative cases about 57 per cent. Since antitoxin these percentages have been reduced to about 15 and 40 per cent. respectively. The lowest annual antitoxin mortality was 10 per cent. and the highest 22 per cent. The incidence of the disease varies greatly—from 279 to 702 cases annually. Of late years the average number of antitoxin units given per head has been recorded, and it appears that for the past four years considerably more antitoxin was required, or at least was exhibited, as compared with previous years. The percentage of cases requiring operation has been cut in two since antitoxin was introduced.

Rupture of the Uterus in a Cesarean Scar.—Schick, who reports a case in point, sums up this subject as follows: His own case was an example of spontaneous rupture during labor at the site of the cicatrix of a cesarean section. The uterus had become adherent to the peritoneum and the placenta was seated over the cicatrix. Accidents of this sort (adhesions) are not rare—in fact this sequela is more to be dreaded than any other consequence of cesarean section. Statistics show seventy-four cases of peritoneal adhesions after cesarean section, and also that adhesions result in 20 per cent. of all cases of this operation. The actual number of cases of scar rupture is not so very large—probably not over two score.

Sputum Examination on Suspicion of Tuberculosis.—Nemmser and Martos-Lissowska refer to cases in which the ordinary methods give negative results. In 300 specimens of this sort they obtained positive results in twenty-one. They employ four tests: I. Alkaline trypsin digestion. To 5 c.cm. sputum in a test tube add 5 c.cm. 0.4 per cent. soda solution and 0.1 c.cm. trypsin or pancreatin. Add two drops chloroform, shake well, and place in the incubator at 37° C. Agitate now and then during the first four or five hours. In from twelve to twenty-four hours a sediment forms. Decant cautiously. Place sediment on slides, dry, and stain. II. Acid trypsin digestion. To 5 c.cm. sputum add 5 c.cm. 0.4 per cent. HCl and treat in the same manner. III. Acid oxidation method. To 5 c.cm. sputum add from 5 to 10 drops hydrochloric acid. Add water to make 10 c.cm. Proceed as before. IV. Autodigestion. Add nothing to the sputum and proceed as before. Only the first test requires chloroform.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

PERSONAL HISTORY.

General Remarks.—It is the plain duty of every one employed by a life insurance company to assist in the conservation of the interests of its policy holders. The idea that a life insurance company is simply an immense money-making corporation run for the benefit of a comparatively few stockholders is fallacious as regards most companies, but is so prevalent that when a company finds it imperative to appeal to a court of justice it is difficult to find an impartial, unprejudiced jury. A life insurance company does exist to save money to a legitimate degree for its policy holders, however, and it would indeed be unreliable and unworthy of the name if its business were not conducted on an economic and conservative basis with that end in view. Among other things, a mortality higher than the normal will cut into dividends to which the policy holders and their beneficiaries are entitled. In order to avoid this contingency there must be a proper selection of lives whose chances of attaining the full limit of longevity are not impaired by present or past disease or injury, or by the results of bad habits.

In securing this personal history the medical examiner is not expected to have the scope of his inquiries limited by the application blank—on the contrary, he is counted upon to get possession of all possible information and to clear up doubtful, ambiguous, or indefinite answers. Each impairment admitted by the applicant should be carefully considered in all its aspects and a searching inquiry should be made as to the cause, symptoms, recurrences, and all possible complications and after-effects. In some cases the cause will be of most interest. For instance, an applicant makes a statement that he had a bilious attack one year ago. Medical directors have learned from experience that a certain proportion of so-called bilious attacks are caused by gallstones or appendicitis. Therefore, the examiner who merely reports the bilious attack and does not indicate that he has made further inquiry and eliminated both conditions in the etiology is sure to have a request from the home office to supply the missing information. In other disorders the important point will be the number and dates of each attack, and possible complications and after-effects, such as rheumatism and gout. In most ailments the examiner will have occasion to use his best judgment and knowledge of diseases in order that he may probe in the right direction for further information and make up a complete and comprehensive report.

The examiner is cautioned against being satisfied with general questions. The applicant, however intelligent and honest, will fail to grasp the underlying meaning of many of the general questions unless they are dissected and explained to him in detail. If he is disposed to conceal facts, general questions afford him an excellent opportunity to evade the issue. Only recently the writer had occasion to interview an applicant who had just been examined and admitted a visit to a health resort in Europe for suspected glycosuria in 1895. He had answered the general question "Have you ever been to a health resort," and it had not occurred to the examiner to inquire more closely. A few additional questions, however, brought out the further admission that he had visited the same resort in 1897 and again in 1899, although even then he tried at first to have it understood that he had not gone for the treatment of any ailment during the last two visits.

The illustration given in the preceding paragraph demonstrates how the medical examiner's relation to the applicant for life insurance is the reverse of that which he occupies in his professional capacity as physician, for, while the patient exposes his infirmities and even intensifies them, the applicant for life insurance may desire to lessen their importance or conceal their existence.

The unwilling applicant, only partially convinced by the agent but persuaded to submit to an examination, is not apt to help the examiner by going into the particulars of his case, and he will occasionally be disagreeable enough to make it a difficult proposition for the examiner to extract satisfactory answers from him. Under such circumstances the examiner will be put on his mettle in getting the desired facts and will not succeed without bringing all his tact and forbearance and, also, his persistence into action. In spite of this attitude on the part of the applicant the report should be made complete, as the agent will usually succeed in placing the policy after he has the examination and other necessary preliminaries out of his way.

The applicant with slight regard for veracity, for the terms of a contract, and for the spirit in which the business of life insurance is conducted is too often encountered. He will glibly tell the examiner, when some admittance has been extorted from him, or when confronted by the fact that he has failed to "give all the truth and nothing but the truth," that he did not suppose it amounted to anything and was not worth mentioning. Or he will remind the examiner that he actually deserves praise for admitting some certain point, as no one would have been the wiser if he had not mentioned it. The examiner should make it emphatically clear to this applicant that the straightforward, honorable way is the only safe one to pursue if he wishes to avoid possible trouble and inconvenience in the future.

The importance of truthful, complete, and correct answers from the applicant in giving his personal history has been dwelt upon for the reason that, aside from the fact that they are necessary before a decision can be given at the home office, the law allows a life insurance company to cancel its policy within a reasonable length of time if it is proved that the applicant was guilty of misrepresentation or false statements in his application. A reputable life insurance company is very much averse to taking such a step, but the interests of the policy holders demand it when palpable fraud is exposed, both for the moral effect produced in deterring others from attempting this evil practice and to relieve the company of a responsibility it could not be expected to assume. There is never the slightest occasion for apprehension in the mind of a policy holder, if he has fully answered the questions truthfully and candidly, that his company will not cheerfully meet every obligation.

In taking up the different subjects under personal history in these columns, emphasis will be laid on the important points to be covered by the questions. An opportunity will be afforded at the same time for explaining the bearing of many of the queries from the home office which seem to the examiner to be irrelevant and uncalled for.

Medical Section, American Life Convention, Annual Meeting Held in Pittsburgh, September 20, 1911. (See page 743.)

Why Should the Results of Examination Not Be Told the Applicant?—Ernst Block says that in Germany the examiner is forbidden to tell results of examination to the applicant or to the agent; yet this injunction is not always followed. Some claim that the examiner is, in the first place, a physician, and should not fail to apprise the applicant, if he finds some disease. However, the mere refusal to accept the applicant for insurance serves as a warning to the applicant, and it is his business to communicate with his family physician in such a case. On the other hand, to tell the applicant that he is acceptable and then have him disappointed, if the insurance company refuses him, is to put his family physician in a bad situation, for he may have been asked to give his opinion of the applicant's health. Therefore, silence as to the results of the examination is the wisest course to pursue. This question had been much debated at the Conventions of German Physicians, in 1894 and 1895, and it was decided that secrecy is the proper course, except that the family physician of an applicant could be apprised in a professional way of any disease discovered by the examiner, which had apparently escaped the former physician's attention.—*Blätter für Vertrauensärzte der Lebensversicherung,* July and August, 1911.

The Qualifications of an Insurance Examiner.—Lissau says that a new science of "insurance medicine" has developed during the last two or three decades; this branch of medicine will surely gain recognition at the universities and some day a chair of insurance medicine may be established. Meanwhile, the insurance examiner must be a self-taught man, so far as his specialty is concerned. He must, however, be well versed in general medicine and especially in the diagnosis of internal diseases. He must be quite a master of percussion and auscultation of the thorax, as he is frequently obliged to decide very weighty questions as to the state of the heart and lungs, without having more than a few minutes for examination. He must have a good grounding in nervous diseases and in dermatology, and also in gynecology. The knowledge of symptomatology of female diseases is of great importance as internal examinations cannot always be made. All this shows that a "general practitioner" and not the specialist is best suited for insurance examiner.—*Blätter für Vertrauensärzte der Lebensversicherung,* July and August, 1911.

Two Unusual Deaths.—A policy holder, 23 years old, gave nothing in his history except nosebleed on one occasion; his physical condition was very good. Three years later he was brought to a hospital in a dying condition with symptoms of cerebral hemorrhage. Autopsy showed this hemorrhage, but no cause for it whatever, so far as internal organs were concerned. No history of accident, excess, or anything that could be brought in connection with the anatomical findings could be learned. Another policyholder died after an unusual accident. Some years ago he choked on a collar button which he held in the mouth; the button finally found its way into the right bronchus and led to almost complete hepatization of the right lung. Several years later the patient had a very severe coughing spell, coughed up the button as far as the larynx, whence it was aspirated into the left bronchus, thus resulting in death from suffocation.—*Blätter für Vertrauensärtze der Lebensversicherung,* July and August 1911.

Orthostatic Albuminuria and Tuberculosis.—Poncet thinks that orthostatic albuminuria is frequently coexistent with pulmonary tuberculosis. He examined one hundred and forty apyretic tuberculous patients, whose urine was free from albumin when they stayed in bed, and found that after one hour's standing albumin appeared in one hundred and two of them. This albuminuria was transitory and appeared more frequently in patients with less advanced disease. Orthostatic albuminuria should be looked for when tuberculosis is suspected; it seems to be an expression of predisposition to the disease.—*Bulletin de la Société Médicale des Hôpitaux,* June 16, 1911.

Insurance Companies and the Fight Against Tuberculosis.—In the year 1909, 29,277 men and 12,995 women were admitted to the sanatoria of insurance companies because of tuberculosis. Many have begun to doubt the wisdom of such wholesale admissions, as improvement was said to be but very temporary, and the results not in proportion to the means and efforts used. The Government insurance office has accordingly attempted to gather statistics bearing on this subject. It showed that of every 100 patients treated between 1897 and 1901 twenty-five men and thirty-two women still showed amelioration; in the period 1904-1908 forty-four men and fifty-one women out of every hundred treated still remained capable of earning a living at the end of the period. Results therefore have improved, and still better things may be expected in the future. Even patients in the third stage of the disease were frequently improved enough to regain some working capacity; others were improved enough to be classified in the second stage of the disease. The costs of the sanatorium treatment amounted from $1.25 to $1.75 per day and patient. The medical value of the treatment seems proved by the above figures. Whether the insurance companies were likewise financially benefited remains to be proved.—*Medizinische Blätter,* No. 47, 1910.

Shipping and Preserving Urine.—Armand Ravold says that many specimens of urine sent by examiners to the home office arrive in bad condition because of improper preservation. Not more or less than an ounce of urine should be sent. The best container is a celluloid bottle made by J. Ellwood Lee Company. Dr. Ravold has experimented with the following chemicals in looking for the best preservative. Acetic acid, chloral hydrate, chloroform, salicylic acid, boric acid, formaldehyde, camphor, sodium bisulphate, thymol, resorcin, sodium benzoate, and toluol. Of these camphor, resorcin, bisulphate of sodium and toluol proved to be valueless for preserving urine containing albumin, sugar, pus or formative elements, which was kept in an incubator for three to five days. Acetic acid, chloroform, chloral hydrate and thymol are only partially efficient. Chloral and chloroform produce a dirty yellow precipitate with Haines' and Fehling's solution, making detection of sugar impossible. Thymol produces a deceptive white precipitate with nitric acid test for albumin. Formaldehyde in solutions of 1-1,000 prevents growth of bacteria in urine and preserves and hardens cellular elements better than any other chemical. Two drops added to an ounce of urine will preserve it for some time. Several drops lead to the formation of a white precipitate of paraformaldehyde when the urine is layered over nitric acid. Small spherical bodies of paraformaldehyde make microscopical examination difficult. Formaldehyde, too, reduces the copper in Haines' and Fehling's solutions. Boric acid tablets found in the market often contains starch or sugar. Pure boric acid inhibits the growth of bacteria, one three-grain tablet being enough for one ounce of urine. Salicylic acid is a good preservative but dissolves very slowly, especially in tablet form. The ideal preservative should be a tablet of low cost; should disintegrate and dissolve quickly in urine; should inhibit growth of bacteria but not interfere with the standard tests for albumin and sugar; it should preserve and harden cellular elements and casts. The speaker said he hoped to report upon such a preservative at the next meeting.—*Proceedings of the Medical Section, American Life Convention, New Orleans,* February, 1911.

Book Reviews.

THOUGHTS OF A CATHOLIC ANATOMIST. By THOMAS DWIGHT, M.D., LL.D., Parkman Professor of Anatomy at Harvard. *"Credidi, propter quod locutus sum."* New York: Longmans, Green & Co., 1911.

"THE acceptance of supernatural religion is something more than the result of an act of deliberate reason. It is an act of faith, which owes its origin to a supernatural gift of God, by which the will accepts what is revealed to the mind." With this the keynote of his theme the late Professor Dwight completed within the pages of this small volume, a labor upon which he had been engaged for many years, namely, the attempt to solve the vital question of the mutual relation of religion and science. He compares religion and science to two planes with a common line of intersection. In discussing the thought of the day so far as this is dominated by the doctrine of evolution he classes Hæckel among the *sans culottes* of science, whose leaders he believes display an unwillingness to tell the whole truth. In the second chapter, the searchlight of criticism is turned on Darwinism, which, apparently retreating before the advance of the mutation theory of De Vries, is said to be fast losing caste among men of science. In the succeeding chapter the author shows that the existence of God can be proved by argument; that design and plan pervade the realm of the living, just as law and order rule the non-living; that the scholastic definition of life is the true one: life is "immanent action," that is action originating within and persisting within, consequently action arising from a non-material force; that the body may be the result of evolution, but the spiritual soul cannot have been evolved; that there is no satisfactory missing link—that many low forms of man, archaic as well as contemporary, are degenerate races, *e.g.* Lombroso's criminal type; that similarity is no proof of relationship; and while there is no clue to the puzzle of variations in their very irregularities they point to law. "Finally, reason by the light of faith tells us that a plan of creation worthy of God must include the supernatural, and be grand beyond human conception." This sentence crowns the thesis whose subtle arguments are garbed in the temperate and elegant diction of the scholar.

THE AMERICAN ILLUSTRATED MEDICAL DICTIONARY. A new and complete dictionary of terms used in Medicine, Surgery, Dentistry, Pharmacy, Chemistry, Veterinary Medicine, Nursing, Biology, and kindred branches; with new and elaborate tables. Sixth Revised Edition. By W. A. NEWMAN DORLAND, A.M., M.D. Flexible leather $4.50 net; indexed $5.00 net. Philadelphia and London: W. B. Saunders Company, 1911.

IN this new edition of the American Illustrated Medical Dictionary a new type has been used and the plan of the more modern dictionaries of printing the titles with initial lower case letter has been copied. These modifications have so changed the appearance of the book as to make it unrecognizable to one used to the former edition, and at the same time the beauty of the old page has been marred. The type is so small as to try the eyes in any but a bright light, and the very broad and black face of the title words, in the absence of leading, gives a blotted appearance to the page. Another feature which the editor has borrowed from the modern dictionaries is that of giving biographical information in connection with eponymic terms. There are, however, comparatively few eponymic terms in the dictionary, as the editor prefers the arrangement of subtitles under "disease," "sign," "phenomenon," etc., and with these the biographical data are not given. In other respects the new edition follows the old ones in both their good and their bad features. The figured pronunciation of the French words has not been changed, and the English speaking physician is still bewildered by the statement that the French termination *ment* should be pronounced like the English *maw*.

GONORRHEA IN THE MALE. A Practical Guide to Its Treatment. By ABR. L. WOLBARST, M.D., Consulting Genitourinary Surgeon, Central Islip State Hospital; Visiting Genitourinary Surgeon, People's Hospital, West Side German Dispensary and Beth Israel Hospital Dispensary; Professor of Genitourinary Diseases, New York School of Clinical Medicine; Member American Urological Association, etc., etc. New York: The International Journal of Surgery Company, 1911.

THIS book reviews the well-known principles of modern gonorrheal therapy and reiterates the wholesome advice and sagacious admonitions of other writers. Such writing is of educational value, but it grows wearisome unless garbed in attractive language. As a book intended for the general practitioner, some of its teachings are of questionable safety. For example, " . . . where the clinical symptoms all point to the existence of an abscess, it is justifiable to look for the pus by the introduction of a trocar through the rectum or the perineum." After discussing the prognosis of clinically cured urethral strictures, he adds: "The patient should have a large sized sound passed at least once, preferably two or three times, every year for the rest of his life." In the chapter on proofs of cure, he writes, " . . . and lastly, one can never tell to a certainty whether any particular patient, once attacked by the gonococcus is absolutely free from latent infection." The greater part of the book relates the methods of treatment, technique and results obtained by various experienced urologists.

LATERAL CURVATURE OF THE SPINE AND FLAT-FOOT. And Their Treatment by Exercises. By J. S. KELLETT SMITH, F.R.C.S. (Eng.), Late Demonstrator of Anatomy at University College, Liverpool, etc. Price $2.00. New York: William Wood & Co., 1911.

THIS is an excellent and most useful little manual, presenting clearly and concisely the steps necessary for the treatment of those cases of spinal curvature which are most likely to present themselves in private practice, and also for the treatment of flat-foot. There is an introductory chapter giving a brief historical review of this subject. The causes of spinal curvature are lucidly described; these concern faulty positions in standing, sitting, and lying, and those induced by wryneck, deafness, and errors of vision, and by extraordinary occupations. There is given a careful analysis of the deformity, while the examination of the spine, the classification of cases, the types of patient, and general directions in the treatment are all adequately discussed. The various exercises described are important, and commend themselves to the general practitioner because of their simplicity and availability for the average patient. The creeping and straight work exercises are particularly valuable. The two chapters on weak ankles and flat-foot present similarly available methods of treating these conditions. The concluding chapter discusses accessory therapeutic measures such as the treatment of anemia and the administration of cod liver oil, etc. The book contains a large number of photographic illustrations that clearly bring out the points described in the text.

ZAHNÄRZTLICHE CHIRURGIE. Von Prof. Dr. med. FRITZ WILLIGER, Director der chirurgischen Abteilung des Königlichen zahnärztlichen Universitats-Instituts zu Berlin. Preis Mk. 4. Leipzig: Verlag von Dr. Werner Klinkhardt, 1911.

THIS manual of 120 pages deals with the subject of dental surgery, as the first number of a series of manuals edited by Professor Bockenheimer of Berlin. This series is intended to cover the entire field of medicine, providing the practitioner with the means of keeping in touch with other branches of practice than the one in which he is particularly interested. The impossibility of digesting a large number of textbooks has suggested the feasibility of providing a series of handbooks in which the essentials of the modern practice in the various branches of medical science are presented. The subject of dental surgery as practiced to-day is one which the general practitioner cannot afford to ignore, touching as it does so many different phases of internal medicine. The present volume deals with this subject in a most satisfactory manner, and awakens a keen appetite for the forthcoming numbers of the series.

SCHUTZPOCKENIMPFUNG UND IMPFGESETZ. Unter Benutzung amtlicher Quellung. Bearbeitet von Professor Dr. MARTIN KIRCHNER. Geheimem Obermedizinalrat und vortragendem Rat im Ministerium des Innern, Mitglied der Wissenschaftlichen Deputation für das Medizinalwesen, usw. Preis Mk. 1. Berlin: Verlagsbuchhandlung von Richard Schoetz, 1911.

THE repeated attempts that have been made to repeal the German compulsory vaccination laws which were enacted in 1874, have stimulated the author to write this manual, in which he shows the beneficent influence which these laws have exerted. He discusses the nature and course of smallpox and its distribution and control, the significance of protective inoculation, the German statutes bearing on this subject, the preparation of vaccine, the technique of vaccination, the operation of the German law, the administration of similar laws in other countries, the antivaccinationists, and a fair presentation of their arguments. Free from the bias which is usually associated with the advocacy of a cause, this book is nevertheless an eloquent plea for the conservation of the State's control of vaccination.

Methodik der klinischen Blutuntersuchungen. Von Dr. Ernst Grawitz, Professor an der Universität zu Berlin, Dirigierender Arzt der inneren Abteilung des städtischen Krankenhauses zu Charlottenburg-Westend. Mit 35 Figuren im Text und 6 Tafeln in Farbendruck. Vierte vollständig neu bearbeitete und vermehrte Auflage. Price, 5 marks. Leipzig: Georg Thieme, 1911.

The technique of blood examination is so specialized that its teaching is usually separated from that of other methods of physical diagnosis, and it is extremely convenient to have this technique presented in the compact form in one volume. This little pamphlet of Grawitz has always been a welcome addition to all clinical laboratories, and now in its fourth edition, with many improvements and admirable colored plates, it furnishes a most useful and complete guide to blood examination. The bacteriology of the blood is naturally not given in any detail, as this is part of another specialty, but all of the other procedures of importance are included.

Kursus der normalen Histologie. Ein Leitfaden für den praktichen Unterricht in der Histologie und mikroskopischen Anatomie. Von Rudolph Krause, A.O., Professor der Anatomie an der Universität Berlin. Mit 30 Figuren im Text und 208 mehrfarbigen Abbildungen auf 98 Tafeln nach Originalzeichnungen des Verfassers. Price, 22.50 marks. New York: Rebmann Company. Berlin und Wien: Urban & Schwarzenberg, 1911.

An abundance of textbooks exists on the subject of histology, some of them having been standards for many years, but no more beautifully illustrated volume than this has appeared at so low a price. Atlases, such as Sobotta's and others, are much more expensive, and do not as a rule give the technical details contained in this book. The work comprises a general and a special part. The general is devoted to a description of the optics of the microscope, the general methods of preparation of tissues for section, the technique of staining and the measuring microscopic preparations. The technical side is sufficiently complete for a beginner; usually one perfectly satisfactory method is given and the rest omitted. For instance, in paraffin embedding, chloroform as a solvent is the only substance recommended, whereas many prefer xylol or (what is probably the best of all) carbon disulphide. The discussion of too many procedures, however, might confuse the student. The special part begins with the finer details of cell structure and then passes on to the simpler tissues: bone, epithelium, cartilage, muscle, nerve, etc., with a very good chapter on the blood. The last part gives the histology of the organs. The illustrative material employed is predominantly human. The striking part of the book is the series of ninety-eight colored plates. These have been done in half-tone, and are in every way superior to anything of the kind that the reviewer has previously seen. An immense amount of manual labor must have been required to engrave the plates, and in no case are there any slips noticeable. The registration also is extraordinarily good. On the whole the plates give the impression of the very best German lithographic work. Such a textbook will certainly prove most useful for classes in histology.

Practical Cystoscopy and the Diagnosis of Surgical Diseases of the Kidneys and Urinary Bladder. By Paul M. Pilcher, A.M., M.D.; Consulting Surgeon to the Eastern Long Island Hospital; Late Surgeon to the German, Seney and Samaritan Hospitals of Brooklyn, N. Y.; Associate Surgeon to St. Johns Hospital of Brooklyn; Attending Cystoscopist to the Jewish Hospital of Brooklyn. Price, $5.50. Philadelphia and London: W. B. Saunders Company, 1911.

The author divides his book into eight parts, the technique of cystoscopy, the cystoscopic examination, the diseased bladder, diseases of the prostate, diseases of the ureter, the functional activity of the kidneys, diseases of the kidney, and therapeutic uses of the cystoscope. These parts are subdivided into sections consisting of from two to nine chapters. In the introduction, the indications for the use of the instrument, its aid in surgical work, and a plea for its more general use are presented. Part I describes the types and construction of various instruments, their advantages and disadvantages and their care. The section contains directions for the preparation of the instrument, patient, operator and room, together with explicit instructions in technique. Sources of error and causes of failure are enumerated and suggestions for their elimination are given. The part ends with a section on ureteral catheterization, wherein are described the usual technical instructions and the maneuvers employed in difficult cases. Part II, as above indicated, is devoted to the diseased bladder. The effects of extravesical pressure, cystitis, vesical tuberculosis, tumors and calculi all receive due consideration. The author presents plates and descriptions of three conditions to which his name is appended, edema trigoni membranosum, edema trigoni simplex, and edema trigoni pseudomembranosum. The first is found in the receding stage of a severe cystitis., the second is found most usually in the irritable bladder, not associated with infection and due to extravesical pressure, the last is an aftermath of severe cystitis and is frequently encountered in women as a result of continued pressure on the trigone. Part IV deals with the pathological changes in the ureter, the results of obstruction from external pressure and stone, and ureteral fistulæ. Röntgen-ray diagnosis in conjunction with ureteral catheterization is considered at length. In Part VI the writer discusses hydronephrosis, tuberculosis and tumors of the kidney, suppurative nephritis, renal calculi, hemorrhages and unclassified diseases of the kidney, outlining their etiology and diagnosis and what may be learned through cystoscopy or ureteral catheterization. The closing section on the cystoscope as a therapeutic instrument is too short and condensed for practical purposes, being a narration of the possibilities rather than a guide in treatment. Occasional inaccuracies such as "acute catarrhal pyelitis of the kidney" are noticeable in the text. The copious illustrations and colored plates so necessary in books of this character are in general good, although Miss Fry has overdrawn those depicting intravesical conditions. The book deserves success because of the excellent arrangement of its mass of information and the author's straightforward, pleasing style.

Lehrbuch der Augenheilkunde in der Form klinischer Besprechungen von Dr. Paul Römer, O.O. Professor der Augenheilkunde; Direktor der Universitäts-Augenklinik zu Griefswald, mit 186 Textillustrationen und 13 Farbigen Tafeln. Price 22 marks. Rebman Company, 1123 Broadway, New York; Urban & Schwarzenberg, Berlin and Vienna, 1910.

Römer's work constitutes a volume of 1028 pages, and is in the form of a series of lectures, the gifted and able author having endeavored to present the subject as he is wont to present it to his students. There is a convenient division of the text into paragraphs and chapters. The text is preceded by a full table of contents; a very complete index follows. The subject of ophthalmology is treated systematically and is complete in the one volume. The style is conversational, the student being led from one phase of the subject to another in logical order. Illustrative cases are interpolated wherever they serve to increase the interest or value of the text. Embryology and anatomy are given in a cursory way only, but physiology, physiological and pathological chemistry, and the etiology of disease as concerns the eye are fully discussed. The descriptions of physiological and pathological conditions are clear and evidence a profound knowledge of the subject. The descriptions of operations are not associated in a single chapter, but are embodied in the chapters that are devoted to the particular part of the eye concerned. Anomalies of the muscles and refraction receive proper attention. There is no bibliography. The work is admirably suited for the use of the postgraduate student who is devoting himself to the study of ophthalmology.

Structure and Functions of the Body. Handbook of Anatomy and Physiology for Nurses and others desiring a practical knowledge of the subject. By Annette Fiske, A.M., Graduate of the Waltham Training School for Nurses. Illustrated. Price, $1.25. Philadelphia and London: W. B. Saunders Company, 1911.

This is the latest addition to the books on anatomy and physiology for nurses (and others), and while it is smaller than some of its competitors, it can hardly be said to be better. The chief fault that we have to find with the present work is that it is too condensed; many of the statements require much more detailed explanation than is accorded them here. For example, the description of the physiological processes of vomiting and of micturition are very meagre and unsatisfactory. The short paragraph on the cranial nerves needs much addition and explanation to make it even approximately accurate. Thus, nothing at all is said of the function of the motor oculi, while the patheticus is said to "control the eye," and the abducens is labeled "a motor nerve." The spinal accessory is said to supply "the muscles of the soft palate." We wonder what the "Nurses and others" will make of such a passage as the following: "The brain, which fills almost the entire cavity of the cranium, is supported by the sphenoid and ethmoid bones internally, as it is protected externally by the other cranial bones." Whatever this may mean, it is certainly peculiarly worded.

Society Reports.

MEDICAL SECTION OF THE AMERICAN LIFE CONVENTION.

Stated Meeting, Held at Pittsburgh, Pa., September 20, 1911.

(Special report to the MEDICAL RECORD.)

THE PRESIDENT, DR. ARMAND RAVOLD OF ST. LOUIS IN THE CHAIR.

The Transmission of Tuberculosis During Fetal Life.—Dr. HAROLD A. MILLER of Pittsburgh, Medical Director Pittsburgh Life and Trust Company, called attention to the importance of the more thorough study of tuberculosis when it occurred in connection with pregnancy, as well as to the neglect of the subject in the past; this neglect was due to the difficulties of finding tuberculous lesions in the placenta where only slight tuberculous changes existed. In some instances as many as two thousand sections were made before evidence of tuberculous changes were found. From a clinical point of view it was concluded that a healed tuberculous lesion did not necessarily become active by the occurrence of pregnancy. Laryngeal tuberculosis was fatal from a maternal point of view in fully 80 per cent. of the cases during pregnancy or the puerperal period. Active tuberculous lesions of the chest became progressively worse without regard to the treatment of the patient in a sanatorium or otherwise and caused maternal mortality of about 60 per cent. during pregnancy and the puerperal period. Hemoptysis did not seem to be more frequent than when tuberculous lesions existed in the non-pregnant or in the male. Hyperemesis permitted a rapid progress of the tuberculous lesion. The pathology of the placenta had been studied from the literature of Schorl, Geipel, Bossi, Sitzenfry, and Warthin, the latter's paper being considered the best and his classification the most acceptable one. The possibility that tubercle bacilli might pass through a defect in the syncytium without leaving evidences thereof and that in the placenta the tuberculous process went direct to primary necrosis without epithelioid or giant cell formation was referred to. The effect on the infant semed to be shown in that the chidren were under the average weight. This underweight did not in itself prove a tuberculous infection as few of the infants showed evidences of tuberculous lesions demonstrable by physical examination and v. Pirquet's reaction gave negative results in 98 per cent. of infants born to known tuberculous mothers. Their method of demonstrating tuberculosis of the placenta was by dissolving the placenta in antiformin, and centrifuging and examining the sediment. In this way many cases showed tubercle bacilli where the microscopical sections failed to reveal evidence of the tuberculous lesion in the placenta. Dr. Miller showed microscopical slides of these placentae which appeared to be perfectly normal, while the centrifuged sediment upon examination revealed the presence of the tubercle bacilli.

Dr. VICTOR C. VAUGHAN, Jr. of Detroit, Mich., Associate Medical Director Michigan State Life Insurance Company, stated that up to this time comparatively few cases of congenital tuberculosis had been reported and the reason for this was very apparent. Although the tubercle bacilli might be present in the placenta, they were very difficult to find under the ordinary methods that were employed pathologically and histologically. Because of the size of the lesion, it would very often escape notice; a great many lesions of the placenta had passed unrecognized and for the reason that in the maternal portion of the placenta one did not find the characteristic tubercle formation. Usually the pathologist judged of the presence of tuberculosis by finding the epithelioid and giant cells, but these were not always present in the maternal portion of the placenta; decidual tuberculosis did not go on to the development of epithelioid and giant cells. The giant cells that were developed from connective tissue stroma and the decidual cells were much modified; they seemed to have no resistance against the action of the tubercle bacilli and could not react in the ordinary way in the formation of epithelioid cells. Sarcomatous tissue, when infected with the tubercle bacilli, would not produce epithelioid cells and behaved in the same way as did the decidua. It was only when the tubercle bacilli gained entrance to the fetal portion of the decidua that there appeared the characteristic tubercle formation with the development of the epithelioid and giant cells. There was no doubt but that the pendulum had swung to the extreme regarding the transmission of tuberculosis during fetal life. At first all were inclined to believe that tuberculosis was a hereditary disease and it was not then considened as an infection. To be truly hereditary the disease must be transmitted by the spermatozoa or the ovum, or the two combined, and this was most improbable.

The most interesting part of the paper pertained to the fact that in cases of comparatively early tuberculosis, that was, cases in which lesions were present although diagnostic sounds were not detectable, tubercle bacilli could be found in the blood from the placenta. The question arose, might this not be a means for the early diagnosis of tuberculosis, especially of the pulmonary type. It was very evident that in the early stages of this disease the tubercle bacilli would lodge in the placental blood and in the intravenous spaces; these were large spaces filled with blood and the tubercle bacilli lodged here. This was a theory suggested by Warthin some time ago, one that was substantiated by Dr. Miller in his paper. There was another thing in connection with tuberculosis occurring in infancy and childhood which was hard to explain, namely, the predominence of bone and joint lesions. With regard to the genital transmission of this disease, there seemed to be an added significance. All sorts of bony lesions occurred in children; in hospitals for the care of tuberculous cases a very large proportion had bone and joint lesions, especially in children under fourteen or fifteen years of age. This was easily explained by the congenital transmission of the tubercle bacilli from the mother through the placenta. For a time the tubercle bacilli lay dormant in the tissues of the child and they expected them to be in the substance of the bone; subsequently, when the resistance of the individual became lowered, they gave rise to a local focus of the disease. Only a short time ago it had been claimed that the tubercle bacilli were found uniformly in the blood of an individual afflicted with tuberculosis; this was, in his opinion, a fallacy. It was true, however, that at times when the lesions were actively developing the bacilli might be found in the blood. It was now fairly well established that a tuberculous woman would develop a more active process during pregnancy; abortions were frequently relied upon in women with a progressive tuberculous lesion. It was probably possible to have children predisposed to tuberculosis without being actively tuberculous, although this was a very dangerous doctrine to put forward. There might be products of the tubercle bacilli produced and transmitted to the fetus when the tubercle bacilli themselves did not pass through; it was possible to obtain a tuberculin reaction in children who did not have an active tuberculosis; in other words, the product might pass from the maternal to the fetal parts of the placenta, thereby ogining an entrance to the fetus itself, while the tubercle bacilli could not. In such cases one might get the v. Pirquet and Calmette reactions a short time after the birth of these infants, but this was not necessarily indicative of tuberculous disease. Warthin and other observers had found in the fetus in which the

tubercle bacilli had been demonstrated in the blood vessels, in the liver and various other organs, that they did not find the characteristic tuberculous formation, Dr. Vaughan congratulated Dr. Miller upon the work that he had done and especially upon what he had said regarding the family history in these cases; certainly a great deal depended upon whether the mother or the father was tuberculous. Tuberculosis in the mother was more important than tuberculosis in the father from the point of view of congenital transmission. Much depended upon whether the mother was actively tuberculous at the time of the birth of her child. It was very difficult to determine whether infection of the infant occurred prior to or after birth. There was no doubt but that all must look upon the congenital transmission of tuberculosis as an established fact and this should be taken into consideration especially in connection with life insurance work.

Dr. E. J. Spratling of Atlanta, Ga., Medical Director of the Empire Life Insurance Company, stated if the mother was actively tuberculous the carrying of a child was a point of great interest to those who were in insurance work. Children born of such a parent seemed to "peter out," a point that Dr. Miller in his paper brought out as being of especial interest to those concerned in insurance work.

Dr. J. S. Langford believed that the transmission of tuberculosis from the father had not been sufficiently emphasized; over and over again the transmission from the mother had been emphasized, but not the transmission from the father; the transmission from the father was as important with regard to tuberculosis as was the transmission of features, and so forth, to the infant.

Dr. A. M. Campbell of Grand Rapids, Mich., Preferred Life Insurance Company, believed that often the mother gave immunity to her child; a child of a tuberculous mother was rendered immune. He asked Dr. Miller's opinion regarding this.

Dr. C. M. Rosser of Dallas, Texas, Medical Director Sam Houston Life Insurance Company, said that the paper read was as important to the world at large as it was to those present. When it was an acknowledged fact that a tuberculous mother was probably capable of transmitting tuberculosis to her offspring, added to which was the hazard of transmission to those about her, it should be easy to engage legislation on this subject; immunity should be granted such women from the possibility of childbirth. From a criminal standpoint the sterilization of a tuberculous woman would be as reasonable and rational as vaccination against smallpox. Dr. Rosser said he was very anxious to learn of Dr. Miller's view with regard to what he would do in considering a risk, one with a tuberculous history and yet who had passed through childhood and early youth. What statements he had made were rather problematical. This was a problem that all Medical Directors met every day; an applicant who had reached the age of thirty or thirty-five, born of a tuberculous mother, he considered a better risk if he had passed through the diseases of childhood and certain debilitating diseases such as typhoid, pneumonia, etc., and had been able to successfully resist them.

Dr. N. A. Olive of Waco, Texas, Medical Director Southern Union Life Insurance Company, said that while listening to the paper and the discussion the histories of two interesting cases occurred to him. The first was one of laryngeal tuberculosis in the mother, very active for probably three months prior to the birth of her child. The child was still-born and the mother only lived six weeks after the birth of her child. The second case was one of pulmonary tuberculosis and the mother lived but one week after the birth of her child. There was no doubt but that a mother in the active stage of tuberculosis, when she was carrying her child, suffered much more from typhoid fever, whooping cough, scarlet fever, etc., because of her lessened power of resistance.

Dr. E. J. Wilson of Columbus, Ohio, Midland Mutual Insurance Company, said that Dr. Miller had demonstrated not only that tuberculosis might be transmitted to the fetus but also the manner in which the transmission took place. Heretofore the notion had prevailed that the spermatozoal infection or infection of the ovum probably was the method of infection of the fetus. With regard to this, he thought the pendulum had swung the other way and such a theory should be discarded. Dr. Wilson was always afraid to insure the lives of children of tuberculous parents; they were more or less impaired and had less resistance; he was especially afraid to take them as good risks when they were at the age at which the mother died.

Dr. John F. Hunter of Jackson, Miss., reported the case of a very markedly tuberculous woman who became pregnant. Her husband and two brothers were tuberculous. She had fever every day and was wasting away rapidly. Several consultations were held and abortion was decided upon. She was given forced feeding, fresh air, sunshine and she gained strength and now weighed 197 pounds and was entirely free from tuberculosis so far as he could tell. At the time the abortion was produced she weighed 117 pounds.

Dr. Armand Ravold of St. Louis, Mo., asked what methods of staining were used to demonstrate the tubercle bacilli.

Dr. Miller replied the acid-fast. Animal experimentation was also employed.

Dr. Ravold believed this was very important; there were other microorganisms which took the acid-fast stain exactly as did the tubercle bacilli. More importance should be placed on whether there was a congenital or an acquired tuberculosis; many of them were not congenital at all but acquired. Many experiments had been carried out with tuberculin on animals and they were of great importance to Medical Directors. Baumgarten had found in the placenta active tubercle bacilli.

Dr. Miller, in closing, said that practically there was no such thing as hereditary tuberculosis; there was probably a direct infection during intrauterine life. The tubercle bacilli gained entrance to the child directly and could be found many times in the mesentery. He regretted that he could not report on more cases. One and six-tenths per cent. of all pregnant women had tuberculosis. It was extremely difficult to get autopsies on children of tuberculous parents. Dr. Vaughan had pointed out the frequency of gland and bone tuberculosis in children; this was to be expected when one considered the osseous and gland tissue in children and how susceptible they were to injuries and infections at that time; they had a different character at this time than they had when they had attained full growth. With regard to active tuberculosis in a pregnant woman, it was always bad and the prognosis was always bad. Infants nearly always acquired tuberculosis through the maternal blood stream when the lesion was active; if the lesion was an inactive one, there were no tubercle bacilli in the blood stream; it was only when the lesion was active and the tubercle bacilli were in the blood stream that the child could acquire tuberculosis. With regard to the father, they were not able to learn whether or not the tubercle bacilli gained entrance through the ovum or through the spermatozoa. He was inclined to the belief that the ovum or the spermatozoa might acquire a certain amount of protection against tuberculosis where the father or the mother or both had recovered from a tuberculous lesion. An unknown something was manufactured and this transmitted to the offspring a certain amount of immunity. In cases of active lesions there was a direct infection from the mother to the child; but whether there was a direct infection from the father was something

difficult to prove. He did not believe that any one man, or any group of individuals, had a sufficient number of cases to prove or disprove the germinal transmission of tuberculosis or, in fact, any other disease. The points brought up by Dr. Rosser were very interesting; the public sentiment should be appealed to and antenuptial examinations demanded. Public opinion has not as yet been educated up to this, to say when a girl or man could or could not be married. They probably would never be able to obtain legislation to control marriages. Antenuptial examinations would never, in his opinion, be permitted except for the control of venereal diseases. Dr. Miller thought that it would be better to consider all children born of tuberculous women with an active lesion as tuberculous children. Only after they had passed through some debilitating disease, such as typhoid fever, should they be considered as standard risks. Every child born of a tuberculous mother with an active lesion he would consider tuberculous and not a good risk; if the child, however, had gone through the diseases of childhood and through some debilitating disease, and had reacted with increase in weight, the applicant would be considered a good risk. Mothers with laryngeal lesions gave them but little trouble because they did not live, nor did their offspring. With regard to immunity conferred in cases of healed lesions, a certain amount might be given; such an immunity might be conferred in much the same way that the features of parents, habits, stupidity, etc. were transmitted. Some years ago measles broke out in the Fiji Islands; the mortality then was very low except from the complications. In 1890 measles caused a mortality of 50 per cent. What was to account for the severity of the disease in Fiji Islands? In this country the mortality was comparatively low. There must have developed something which caused a certain amount of immunity in the offspring.

The Healed Tuberculous Lesion from a Life Insurance Standpoint.—Dr. GEORGE W. PARKER, Medical Director Peoria Life Insurance Company, read this paper, in which he said that tuberculosis had been a bugbear to insurance companies ever since their incipiency. The United States Census reports gave tuberculosis as a cause of more than 10 per cent. of the death rate and its occurrence was much more frequent than these figures showed. They had gained their most comprehensive knowledge of tuberculosis from postmortem statistics and a review of the literature on this subject taught that the majority of all applicants applying for insurance had either active or healed or latent tuberculosis, that postmortem findings proved conclusively that tuberculosis could heal, and that the average age of the healed lesions in Adami's and McCrae's one thousand autopsies was 46.2 years and of latent cases 38.7 years, and that the average age of the active cases was less than that of the latent. The forms of tuberculosis that were interesting from a life insurance standpoint were pulmonary, bone and joint, glandular, genitourinary, and skin lesions, and fistulæ. Under pulmonary tuberculosis, pleurisy, bronchitis, hoarseness and hemoptysis claimed attention. The majority of all cases of pleurisy were tuberculous. As proof of this statement the following points might be stated: (1) Postmortem evidence showed that tubercles had been found in acute cases thought to be rheumatic; (2) according to Aschoff, 68 per cent. of animals inoculated from cases of serous pleurisy succumbed to tuberculosis; Le Damany found that from 86 to 96 per cent. thus inoculated succumbed; (3) in pleurisy mononuclear leucocytes predominated; (4) a large percentage of cases of pleurisy gave positive tuberculin reactions; and (5) the subsequent history of these cases showed, according to Bowditch, that of 90 cases followed 30 years, 32 developed tuberculosis, according to Hedges, 130 cases with effusion followed seven years, 40 per cent. became tubercular; according to Cabot, 221 cases followed 5 years, 117 developed or died of tuberculosis and, according to Hamman, of 562 cases, 167 or 29.7 per cent. became tuberculous. In exceptional cases the pleurisy was primary, but it was most frequently an extension from a tuberculous lung or from the peribronchial glands. The large number of pleural adhesions found at autopsy showed that pleurisy healed. In passing on a case of former pleurisy, even though the applicant was well at the time of examination and had been apparently well for a number of years, he should be considered as having had tuberculosis of the lungs or peribronchial glands at the time of the pleurisy, unless it could be definitely proven otherwise. When a history of bronchitis, "cold on the chest," pneumonia, or hoarseness was obtained it should not be forgotten that these might be symptomatic of tuberculosis and suspicion should be aroused by the duration of the attack, its frequency, the family history, weight or other symptoms of tuberculosis. A previous tuberculosis might come in on an examination blank as malaria, neurasthenia, overwork, indigestion, fever, anemia, grief, etc., and in lightweight subjects these terms should arouse suspicion. The symptom of hemoptysis was closely linked with tuberculosis of the lungs and was diagnostic in a large number of cases, as was shown by a study of the statistics. Statistics also showed that hemoptysis could occur without other evidence of the disease and that it was very frequent as an initial symptom. As an early symptom Anders stated that of 2,084 cases, 1,439 or 68 per cent. showed hemoptysis in the first stage and early part of the second, or that of softening and ulceration. The experience of a large old-line company as given to the writer in a personal letter stated that of somewhat less than 500 cases insured between 1897 and 1908 there was mortality of 14 points above the general average of the company on all its business for the same period. Among those having hemoptysis a higher mortality was shown among those in the younger ages. In regard to bone and joint tuberculosis, if there was in these lesions a primary localization to the bones or joints, it would be much easier to handle them from an insurance standpoint, but in a great majority of cases these lesions were secondary. Koenig stated that from his experience in postmortem work 79 per cent. of bone and joint tuberculosis was one of multiple foci. From their point of view it was proper to consider bone and joint tuberculosis as a single manifestation of a multiple infection. Recurrences after clinical healing were of frequent occurrence, especially after trauma. Some authorities claimed that in apparently healed bone lesions there would be recurrence within fifteen years; others, before the age of forty-five Billroth stated that 27 per cent. of all cases of tuberculosis of joints died of tuberculosis Koenig found a mortality in four years of 16 per cent. in 117 cases operated upon. In 1903, 34 companies examined a number of applications where the applicant had died of hip-joint disease, and the mortality was 28 points above the fair average risk. The percentage of actual to expected deaths in the case of hip-joint disease averaged 127.9. The percentage was higher below 42 years of age, being 132.3. Under the head of glandular tuberculosis they had to deal mostly with cervical lymph glands. This was frequently the only lesion in the body and it followed that if the glands were removed early in the course of the disease it was less probable that multiple foci would develop. The statistics showed that those who had passed five years in good health after an operation need have little fear of recurrence. Cases giving a history of radical operation by a competent surgeon, before the infection became localized in other regions, would give better results as to mortality than those that had healed without operation. In discussing tuberculosis of the kidney and testicle, which were nearly always secondary to other foci of infection, there

was a large percentage of relapses which would exclude the apparently healed lesion from the insurance standpoint. In skin tuberculosis systematic infection was liable to occur. In lupus, recurrences after apparent cure were frequent. Besnier stated that 21 per cent. of his lupus cases died of consumption. Fistula in ano was definitely known to be tuberculous in 40 to 50 per cent. of all cases. One of the largest companies stated that in somewhat less than 500 cases operated on for fistula and insured between 1893 and 1908 they had a mortality of 14 points above the general average of the company for all of its business for the same period. The writer thought that if the fistula appeared to be primary and if the fistulous tract was thoroughly excised it should heal permanently in almost all cases. At present there was a lack of statistical material from which to construct clear and definite rules for the acceptance of lives impaired by previous tuberculosis. Some 42 companies were at present engaged in combined statistical report which would include healed tuberculous lesions. In deciding upon the acceptance of an applicant with a past tuberculous history the following points should be considered: 1. The length of time since the lesion was active. This would vary from 5 to 15 years or more. 2. Freedom from all tuberculous symptoms during this time with the usual capacity for work. 3. Best weight—weight at the time the lesion was active and the present weight. 4. Family history and personal association with tuberculosis since that time. 5. Occupation and station in life. 6. Age. 7. Temperature test—evening temperature, temperature after exercise. 8. Pulse rate. 9. Present condition of health as determined by a careful physical examination.

Dr. Calvin H. English of Fort Wayne, Ind., Medical Director Lincoln National Life Insurance Company, said that what he had to say would be only from the point of view of how these risks affected the life insurance business from a medical standpoint and also how these unfortunate people might be affected by life insurance companies. It was a well-known fact that all life insurance companies had more or less hard and fast rules which were laid down for the acceptance or rejection of those who gave a history of a tuberculous lesion and also those who had been exposed more or less directly to the infection. These rules were certainly very arbitrary and admitting the best possible judgment, backed up by all the knowledge that could be obtained on the subject, yet he was convinced that in the disposition of many of these cases they unfortunately caused an injury, not only to the company but to the applicant as well. There were many things to be taken into consideration; there were many things that were not known and could not be known at the time the risk was presented to the company because the applicant's life had not been lived. No one could doubt the influence of financial reverses, the loss of some particular friend or some domestic unhappiness or other misfortune as having a bearing on the advisability of insuring an applicant. There were many other things which would fan into a flame these smoldering embers that had lain quiet for quite a long time, apparently abiding their time. He was inclined to believe that very little attention had been given to this particular feature in the acceptance of most of their risks; after a very diligent search of the literature he said he had found but very little written on this subject. He contended that with their present methods of selecting their examiners, coupled with the latter's incompetency and careless attitude in many cases, it was quite impossible to intelligently segregate and select who should and should not be granted insurance. Was it not the high potential quality of the soul in an individual that was able to take on sufficient nutritional force to keep him near the standard weight, coupled with a happy, cheerful and hopeful disposition, that would successfully carry him through life, to die of old age? Many of the applicants were rejected risks who had been associated with tuberculous people, and who also had evidences of having had tuberculous lesions and who had lived out their expectancy; they should have been granted their insurance at the time they presented themselves. In this way harm and injury was done to the people. But the proportion of these cases was very small; they had to exclude practically all of these in order to be safe. On the other hand they were furnished with very reliable information from many of the European morgues, where very careful and painstaking research was made and where the postmortem was held in every case regardless of the cause of death, that everybody living to the age of thirty had been infected and some demonstrable lesion of tuberculosis existed. Out of this the insurance companies expected them to select their risks; how could they intelligently do it? Hereditary conditions, environment, hygienic and sanitary conditions in the surroundings of the individual played such an important part that it appeared to be impossible to make a reasonable and safe selection. And yet from these carefully selected risks they found tuberculous lesions where the infection had occurred early in life. Dr. English called attention to the large cost to the nation as a result of the deaths from tuberculosis. In the State of Indiana alone during the year of 1910 there were 4,492 deaths from tuberculosis, 1,913 males and 2,579 females. The number of orphans as a result of these deaths from tuberculosis numbered 2,590. The estimated approximate cost to the State in caring for these orphans until they became of age was $2,100 per orphan, or a total cost to the State of $10,000,000 annually. This applied to the State of Indiana alone. What an enormous loss to the entire United States. Would it not be better and wiser to employ this large sum of money in an effort to stamp out this disease? Was it too much to hope for a time when they should not longer hear of deaths from tuberculosis? He thought not. He believed that such a large fund could be handled wisely by a national or state organization, with county and town secretaries of boards of health. The people should be educated; men and women should be employed who would go into every city and village and hamlet, every school house and church, teaching the people the necessity of better hygienic and sanitary living. He said he would like to see this convention go on record as favoring the expenditure of such money by the nation and state. Information regarding pulmonary and laryngeal tuberculosis should be spread broadcast; such patients should be isolated and infection of others prevented. Would it not be wise for insurance companies to put forth what they could to assist national and state organizations, or through other possible channels, the dissemination of this knowledge in the matter of the prevention of tuberculosis; they must conclude that after all the question was one of prophylaxis.

Dr. Victor C. Vaughan, Jr., of Detroit, Mich., Associate Medical Director Michigan State Life Insurance Company, speaking of pulmonary tuberculosis, said that it appeared that an exceptionally optimistic view had been taken recently. If patients were placed under improper conditions the disease would become active; the tubercle bacillus was an obligate parasite and preferred to live in the animal body and in harmony with its host. It had not a chance to kill the individual but to live with it and, for this reason, one probably would find a great deal of difficulty in establishing an immunity in tuberculosis. Undoubtedly this was one of the principal things in the treatment of the disease; it was a recognized fact that it was necessary to build up the general health of the individual, and direct efforts toward increasing the resistance of the patient; this was of more importance than attempting to do much by so-called specific treatment. Every case of

tuberculosis should be treated as an individual case. It was very hard to tell what the outcome was going to be in any case. Tuberculosis in one individual was a disease in that individual, and it depended upon that individual what the outcome was to be. This was true of all chronic diseases. For this reason in pulmonary cases it was undesirable to look upon any case as completely and absolutely cured. They might be cured to all intents and purposes, but when placed under certain conditions they were liable to recurrences. It would be advantageous if the individual could come to an expert in *x*-ray work and subject himself to such examinations. It was important that he should go to an expert in this work, one who could properly interpret his findings.

Dr. Mason M. Lairy of Lafayette, Ind., Medical Director Lafayette Life Insurance Company, said that the patients' statements that they were well after a short time in sanatoria was not to be relied upon; they were not able to interpret their symptoms. Therefore one should be careful in making any expression as to the curability of these risks. Some years ago he had spent a summer with Dr. Trudeau at Saranac Lake who said, "Do not regard these patients as normal individuals, the so-called cases of arrested or cured tuberculosis." He did not believe in the use of this expression, "cured tuberculosis." He regarded them as cases of arrested tuberculosis. Under proper conditions and proper surroundings such patients might live for years.

(To be continued.)

THE AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

Twenty-fifth Annual Meeting, Held at New York City, May 31 to June 3, 1911.

The President, Dr. Charles L. Gibson of New York, in the Chair.

Disease of the Verumontanum.—Dr. E. Wood Ruggles of Rochester, N. Y., said the etiology of disease of the verumontanum was generally gonorrheal, although excessive masturbation, coitus, or prolonged sexual stimulation without gratification might cause it. One of the most pronounced symptoms was frequency of urination. Most of the patients complained of an unpleasant sensation of heat or pain in the urethra or the neck of the bladder, or the pain might extend to the lumbar and sacral regions. A particularly characteristic symptom was that of extreme sensitiveness of the posterior urethra to the passage of sounds, and a frequent sequence was the development of impotence. There was frequently severe mental depression, which, unrelieved, tended to end in grave sexual neurasthenia. Nitrate of silver was specific in most cases, but not in low dilutions. A 1 or 2 per cent. solution gave rise to great distress, and accomplished little or nothing, while swabbing with a 10 or 20 per cent. solution of silver nitrate caused very slight discomfort as soon as the urethroscope was withdrawn. Of late, the speaker said, he had used small pencils of lunar caustic in place of the silver nitrate solution. The effect seemed to be superior, if anything, and the reaction following their use was much less severe.

The Complement Fixation Test in Gonorrhea.—Dr. George K. Swinburne of New York regarded this new test of the blood as the most important advance made in years in the study of gonorrhea.

Results Obtained by Treatment of 211 Cases of Gonorrhea and Its Complications by Means of Gonococcic Vaccines and Antigonococcus Serum.—Dr. Orville Horwitz of Philadelphia concluded that, beyond occasionally relieving patients who were suffering acute pain, vaccination was worthless. The serum was of service only occasionally in severe cases of epididymoorchitis and gonorrheal myocarditis. In acute and subacute arthritis it should always be used as a routine treatment. In those rare cases of pure gonorrheal toxemia it was invaluable. A study of his tables showed that, of 211 cases treated, 22, or 10 3/7 per cent., were cured; 9, or 4 2/9 per cent., were improved, leaving 180, or 85 3/10 per cent., uncured. Of the 211 cases, 96 were treated with vaccine and 115 with the serum.

Comparative Value of Some Urethral and Other Germicides.—Dr. J. Bayard Clark of New York showed that the killing power *in vitro* of the various silver salt preparations was weak or *nil* as compared with the action of silver nitrate.

Dr. Swinburne said he had used the newer silver preparations for a number of years, and he was prepared to state that if they were resorted to within twenty-four hours after the onset of the discharge in primary gonorrhea 90 per cent. of the cases could be saved from posterior urethral complications; that if used within forty-eight hours after the onset of the discharge 70 per cent. could be saved from such complications, and that if used within three days after the onset of the discharge at least 50 per cent. could be spared from posterior infection.

Dr. L. Bolton Bangs of New York said he was quite unwilling, with Dr. Swinburne, to give up the use of the newer silver salts. He was not in a position at the moment to state definitely his percentage of cures with these remedies, but he was quite unwilling to give up the experience he had acquired in the use of the silver salts in preventing or aborting or certainly modifying so virulent a disease as gonorrhea.

The Treatment of Urethral Gonorrhea in Women.—Dr. E. Wood Ruggles of Rochester, N. Y., said the ordinary treatment of urethral gonorrhea in women left much to be desired. In the first place, the urethra itself was rarely given any attention whatever, although in the large majority of cases it was the only structure primarily invaded by the gonococcus. Later, of course, if the infection was not eradicated, it was likely to extend to the cervix, tubes, and ovaries. As a rule, the vaginal douche was the only treatment prescribed, and even when gonococcidal remedies such as protargol or argyrol were used, they did not penetrate the urethra. When the patient was discharged, on the disappearance of the vaginal discharge, a chronic urethral gonorrhea frequently persisted, often indefinitely. The treatment of urethral gonorrhea in women, to be at all effective, must be administered at least once daily. The patient was to inject herself with a protargol solution, the strength being, as a rule, 1 per cent., although in a few instances this was too strong and a ½ per cent. solution was substituted. For the purpose of injection an ordinary, blunt, three-dram urethral syringe was used. The success of the treatment depended upon the care employed in the instruction of the patient, and this was preferably to be imparted by the office nurse.

The Report of One Hundred Cases of Syphilis Treated with Salvarsan.—Dr. F. C. Edgerton of New York stated that he had never found any drug which healed the syphilitic lesions so rapidly and so satisfactorily as salvarsan. When one realized that the chancre, the mucous patch, and condylomata lata were in the majority of cases healed over in forty-eight hours, and as these were the active carriers of contagion, one would readily agree that the spread of syphilis would be greatly diminished by the use of this drug. A second injection should be given in practically every case within three weeks after the first, excepting in those cases where there had been some bad effects following the first injection. The speaker preferred the intravenous method of giving the drug, because the disappearance of the symptoms seemed more rapid, there was neither pain nor local irri-

tation at the site of the injection, and the effects of the salvarsan had proved to be more lasting and recurrence less frequent. As to the absolute certainty of the cure, sufficient time had not elapsed to justify the conclusion that one, or even two or three injections of salvarsan would prevent recurrences of the disease, either of the secondary or tertiary lesions. Time alone would tell.

Note on the Final Result in a Case of Hypospadias after Beck's Operation.—Dr. ALFRED C. WOOD of Philadelphia said he had employed Beck's method in four cases, all of the balanic type. In two the immediate results appeared to be satisfactory. In one the urethra retracted partially and a fistula formed at the coronal sulcus, requiring a second operation for its closure. The fourth case resulted in complete failure; the stitches all cut out, and the urethra retracted to its former position.

Two Cases of Vesicointestinal Fistula Due to Diverticulitis of the Sigmoid.—Dr. ARTHUR L. CHUTE of Boston said he had recently had the opportunity to see and study two cases of vesicointestinal fistulas due to diverticulitis of the sigmoid. In a very large proportion of the cases in which pouchings of the sigmoid were found at autopsy there had been during life no symptoms referable to the condition. The actual cause of these diverticula was probably an increased pressure in the bowel, due to constipation or an increased formation of intestinal gas. General atony of the muscular coat of the bowel had been suggested as the predisposing cause, as had also some congenital defect of the bowel wall, but, in the light of the fact that these diverticula were most often found in the epiploic appendages, the most probable predisposing factor seemed to be that suggested by Bland-Sutton, whose view was that there was often a fatty infiltration of the bowel wall just under these appendages which weakened it at this point, thus allowing a hiatus of the mucosa to take place. The symptoms of vesicointestinal fistulæ were the passage of gas by the urethra, feces, and the passage of urine by the rectum. The commonest symptom was pneumaturia, but this was not definitely diagnostic, as were the other two signs, since infection where the urine contained sugar might bring about a gas formation by splitting up the sugar. The passage of bowel contents was definitely diagnostic of a communication between the intestines and the urinary tract.

Bladder Atony and Prostatectomy.—Dr. HORACE BINNEY of Boston reported in detail two cases of prostatic hypertrophy with complete retention and with no evidence of nerve lesions, in which prostatectomy failed to cure the retention. In considering these failures to relieve retention, the question at once arose whether actual atony existed, or whether some other cause was responsible. There were three other possible causes of failure: First, obstruction at the bladder outlet or in the prostatic urethra by a bar, a flap of mucous membrane acting as a valve, or a remnant or lobe of prostatic tissue which was overlooked. Second, a diverticulum of considerable size or a condition of marked sacculation. Third, lesions of the ganglia or nerves controlling the bladder muscle and sphincters. In regard to the two cases reported by the author, the first cause could be excluded by the suprapubic operation in the first case and two cystoscopic examinations in the second case. The second cause, diverticulum, was lacking in any important degree in the first case, the minute opening seen with the cystoscope being invisible at the suprapubic operation, and the second case showed no sign of such a condition. In fact, only slight trabeculation was present. Neither case gave a history of syphilis or showed any signs of tabes or other nerve lesions. The speaker was forced, therefore, to fall back on an atonic condition of the bladder muscles to explain these failures.

A Case of Dilatation of the Ureters.—Dr. J. BAYARD CLARK of New York reported this case, with radiographic illustrations.

Further Observations on High Frequency Cauterization of Bladder Lesions.—Dr. E. L. KEYES, JR., of New York said that, since the publication of a preliminary paper upon the treatment of bladder tumors by the high frequency current a year ago, it had been found that the single pole, or Oudin, current was far more efficacious in the treatment of these lesions than the D'Arsonval current, which he was using at that time. The superior efficacy of the Oudin current was due certainly to the greater convenience of its application in the bladder, and perhaps, also, to a superior electrotherapeutic quality. The apparatus required was a cystoscope with ureter catheterizing connections, an electric machine for the production of the high frequency current, and an insulated wire sufficiently small to pass through the ureter catheter channel. Dr. Keyes then described the technique of the method in detail, and reported ten cases in which he had resorted to it. He stated that the results obtained from this treatment in papilloma of the bladder had been most gratifying. The effect of the current upon infiltrating carcinoma was apparently *nil*. He had tried the treatment after the method suggested by Dr. Edwin Beer upon two cases of prostatic hypertrophy without result. In three cases of bladder ulceration it had also given unsatisfactory results, and he had been rather disappointed in the effect of this method of treating the engorged verumontanum.

Operative Treatment of Carcinoma at the Fundus of the Bladder.—Dr. FRANCIS R. HAGNER of Washington, D. C., reported four cases upon which he had operated during the past sixteen months. All excepting the first were operated on as described by him in the *Annals of Surgery*, November, 1910.

A Case of Cystitis with Multiple Ulcers Cured by Excision of the Ulcers.—Dr. FRANCIS R. HAGNER reported this case.

Malignant Papillary Adenoma of the Kidney.—Dr. J. BENTLEY SQUIER of New York reported this case in detail, and showed the patient and pathological specimen.

A Case of Early Cancer of the Bladder.—Dr. RICHARD F. O'NEIL of Boston reported a case which presented several features of special interest, one being the short time which elapsed between the onset of the symptoms and the performance of the operation, which was five weeks from the first appearance of hematuria and six weeks from any other urinary symptoms. Another point was the slight amount of infiltration present and the fact that carcinoma existed in one or two small areas only. There were not many transperitoneal operations as yet published which had been done for cancer, most of them having been for various other types of bladder tumors, principally papillomata. From the few series of transperitoneal operation which had been found reported the immediate operative results had been good.

Phenolsulphonephthalein as a Test of Renal Function.—Dr. HUGH CABOT and Dr. EDWARD L. YOUNG, Jr., of Boston presented a critical study of 117 cases upon whom 169 tests had been made. The following conclusions were offered: From their study of this test they believed that the claims of Rowntree and Geraghty could be substantiated. They regarded it as simple in technique and more accurate in its results than any of the other tests of renal function. Their observations up to this point left them in doubt as to the accuracy of the test in chronic nephritis, and they thought that further study was necessary. They believed the test to be of great value in cardiorenal disease in indicating the organ principally or most importantly affected.

Report of a Case of Bilateral Nephrotomy for Renal Calculi.—Dr. F. C. EDGERTON of New York reported a case of double nephrotomy which was performed for the removal of renal calculi. The kidney that was considered

to be in the best condition was operated on first, the speaker feeling that, in case the other kidney had to be removed at the time of the second operation, the patient would have one good kidney left. The rapidity with which the chronic pyelitis healed after the removal of the stone, when it had existed for nearly ten years, was shown by the fact that to-day the patient's urine was absolutely clear, containing no pus cells.

Further Facts Regarding the Relation of Tuberculosis of the Kidney to Tuberculosis of the Lungs.—Dr. JOHN H. CUNNINGHAM, Jr., of Boston after reviewing a previous paper on this subject, stated that further experimental work was undertaken to determine whether or not the tubercle bacillus was eliminated from the general circulation without producing tuberculosis of the kidney. In these experiments guinea-pigs were inoculated with urine normal by analysis taken from male patients with advanced tuberculosis of the lungs. In the previous communication there were 25 such inoculations with but a single positive result. That patient was cystoscoped, and the bladder urine and the urine from both kidneys showed no tubercle bacilli by smears or on further inoculation. The patient was still living and his urine had remained normal. This evidence seemed to point to a contamination somewhere in the first experiment. Taking the two series of cases together, there were 66 patients with advanced tuberculosis of the lungs, the urine from whom, when inoculated, showed six positive results. The repetition of the inoculations of the urine collected from these patients by means of the cystoscope and ureteral catheters failed to corroborate the early findings in four of the positive cases. One of the positive results might be attributed to genital tuberculosis, and no definite conclusion could be drawn in regard to the remaining patient, who died without further examination, or an autopsy to confirm the early findings. Even accepting this single questionable case as positive, one had but a single instance of the elimination of tubercle bacilli through the kidneys in a series of 66 male individuals with advanced tuberculosis of the lungs and normal urine by the usual methods of uranalysis.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held February 9, 1911.

DR. WILLIAM SHANNON IN THE CHAIR.

Multiple Abscesses in One Kidney in a Child.—Dr. JOHN DOUGLAS presented a child, 7 years of age, who was admitted to St. Luke's Hospital on November 15, 1910. Her family history was negative. For three months she had complained of pain in the right side on exertion, especially when climbing stairs. She had complained of headaches, lassitude, slight fever, loss of appetite and loss of weight. At times she had pain on urination, but had passed no gravel, stones nor blood. The urine was, however, occasionally cloudy. Two days before admission to the hospital she had been seized with severe abdominal pain and vomiting. She had also had a chill, followed by high fever. The bowels were moved by glycerine suppositories; no blood was found in the stools. At the time of admission her temperature was 103.4° F., and pulse 144, with respirations 40. There was a high total and polymorphonuclear leucocyte count. A tender mass was found on the right side of the abdomen slightly above the umbilicus. Over the mass was a dull tympany and it was thought that she had a retrocecal appendicular abscess although suppurative kidney lesion was considered. At operation a markedly thickened appendix presented itself, and this was rapidly removed. This mass proved to be the right kidney, two or three times the normal size, and studded with necrotic abscesses which varied in size from a pin head to a centimeter in diameter. The pelvis of the kidney was distended and held about 100 cc of cloudy urine. Nephrectomy was performed. The temperature fell rapidly after the operation and there was no subsequent infection of the wound. The child was discharged cured at the end of three weeks. This case was of interest on account of the age of the patient and the possible hematogenous infection of the kidney occurring in a child who had not previously had some acute infection as an etiological factor. The history of the case seemed to indicate that there might have been a displacement of the kidney with perhaps intermittent hydronephrosis, the displaced kidney being in a position where it was subject to traumatism, an etiological factor in acute hematogenous infection of the kidney. On the other hand the microscopical appearance of the specimen, showing numerous hemorrhagic areas studded with miliary abscesses, seemed to indicate a hematogenous infection; the dilated pelvis together with the previous history of cystisis, fever, malaise and lumbar pain would point to the probability of the lesion being the result of one of those cases of pyelitis due to colon bacillus infection which quickly subsided under treatment with urotropin. The pathological examination had not cleared up the point concerning the route of infection, whether ascending or hematogenous.

A Case of Disturbed Function of the Thyroid Gland: Hyperthyroidism and Hypothyroidism in a Girl Ten Years of Age.—Dr. SIDNEY V. HAAS presented this patient, a Russian, whom he had seen at the Vanderbilt Clinic in October, 1909. She had always been backward in her studies and had nocturnal enuresis. Her tonsils and adenoids had been removed three months before. For a period of two or three years she had been under the care of a number of physicians for an indefinite condition, the symptoms of which were pain in the abdomen, vomiting after meals, loss of appetite, constipation, headache, tenderness of the scalp, redness of the conjunctiva, pain in the eyes and sore throat. The physical examination showed a pale, irritable, crying girl, who feared and resisted examination. Slight exophthalmos and congestion of the conjunctiva were present. The right lobe and isthmus of the thyroid were visibly enlarged. The circumference of the neck was 27 cm. The scalp was exceedingly tender. The apex beat was in the fifth interspace, three-quarters of an inch to the right of the sternum. There were no murmurs. The abdominal wall was relaxed and there was no axillary nor pubic hair. A diagnosis of hyperthyroidism was made. Catharsis followed by iron was ordered. Seven months later the girl again appeared at the clinic and reported that she had felt well until a week previously when she began having headache, constipation, vomiting and pain in the abdomen. She was less excitable and the exophthalmos was less marked. She had gained sixteen pounds in seven months. She appeared again about six months after this with the same symptoms as before. A diagnosis of hypothyroidism was now made, and the patient was placed in the Lebanon Hospital for observation. The examination of urine and feces proved negative. The erythrocyte count was 4,900,000; the leucocyte count 11,000, with polymorphonuclears 62 per cent.; lymphocytes 38 per cent. The von Pirquet test was markedly positive. The *x*-ray examination showed enlargement of the heart, but no enlargement of the thymus. At the present time the patient's condition was better than at any time since she had come under observation. She had gained 34½ pounds in fifteen months, and now weighed 106 pounds. Dr. Haas had presented this case because they had here a picture of: I. Hyperthyroidism, or exophthalmic goitre, with the classical symptoms of, (a) exophthalmos, (b) enlargement of the thyroid gland, (c) hyperexcitability, (d) a moderately rapid pulse, (e) loss of weight. 2. Hypo-

thyroidism, myxodema, with the symptoms of (a) mental and physical dulness, (b) rapid increase of adipose tissue in irregular masses, (c) pallor. 3. Stage of balance, a disappearance of the myxedematous characteristics even though the weight was increasing. That other glands beside the thyroid were involved was probably true; there could be but little doubt that the recurrence of gastrointestinal disturbance was a part of the pathological condition. This case illustrated the fact that many minor disturbances of the thyroid gland were probably unrecognized.

A Case of Streptococcus Infection in a Child Two Years Old.—Dr. MAURICE OLIVER MAGID asked for an expression of opinion regarding this case, a boy two years of age, who was suddenly taken ill after eating sausage. He had a temperature of 104° F. and marked rigidity of the right side of the abdomen. He was carefully watched for a day and then sent to the hospital with a diagnosis of possible appendicitis. A normal appendix was found, but the peritoneal cavity was found to be filled with pus and streptococci. The cause of the peritonitis was not known and autopsy was refused

Dr. L. E. LAFETRA said he was much interested in this patient, as he had seen him many times.

Notes from the Children's Service in the Presbyterian Hospital, with Exhibits.—Dr. WILLIAM P. NORTHRUP said that certain things had occurred in his experience at the Presbyterian Hospital which might be worth while presenting. He told of his experience with vulvovaginitis and of the necessity of closing one of his wards. After an attack of measles he very much feared vulvovaginitis developing in these children.

Dr. Northrup described the "baby washer," which was similar to a Turkish bath: The babies were washed on a slab, as he demonstrated on the blackboard. Liquid castile soap was used and the wash-cloth always destroyed. A tank holding 80 gallons of water was in use. The temperature of the water was 103°. It was so arranged that the hot water went down and the cold was forced up and the temperature required was thus produced.

Dr. Northrup also showed an asbestos box with an electric heater attached, and demonstrated what took place in an incubator. It was a simple contrivance, and there was no danger of burning the baby. He also described a so-called "grill" which had been introduced in Paris; it was in reality a wire fence around a ward.

Dr. HENRY KOPLIK said that in choldren's hospital service it was very necessary to watch details; this was requisite for the best interests of the patients. Everyone had his own ideas. Recently he had received a letter from a party in another city in regard to the cribs used; it should be thoroughly understood that the crib should be made so that the child would be comfortable. Dr. Koplik did not think it was necessary to exclude cases of vulvovaginitis from the ward; this disease was rarely spread in spite of what was said to the contrary.

A Collected Study of Sixty Cases of, and Conditions Simulating, Meningitis, with Special Reference to Diagnosis.—Dr. ABRAHAM SOPHIAN read this paper, which was the result of work done in the Research Laboratory of the Health Department under the direction of Dr. Park. During the past six months Dr. Park had undertaken the study and treatment of cases of meningitis in this city, including the preparation and distribution of meningitis serum. During this period sixty cases had been studied clinically and bacteriologically. The clinical diagnosis of the bacteriological cause of various forms of meningitis had often differed from that established by laboratory findings. The difficulty and resulting errors in private practice in establishing a true etiological diagnosis as to the type of meningitis and in differentiating between meningitis and meningism had been forcibly impressed upon the author, and he presented tables showing comparative clinical diagnoses and true bacteriological diagnoses and indicated a number of the more important clinical data which he had found of considerable value in establishing a clinical diagnosis before lumbar puncture was done. From a study of the first table it was evident that of the true inflammations of the meninges, tuberculous meningitis was most frequently met with and was also most frequently confused with other forms, especially with epidemic cerebrospinal meningitis. Of conditions simulating meningitis he found bronchopneumonia in children, especially those forms with apical lesions, most often mistaken for meningitis. Other conditions were gastroenteritis, acute infections such as typhoid, and affections of the central nervous system such as cerebrospinal lues and anterior poliomyelitis. In the majority of cases tuberculous meningitis could be diagnosed clinically. The patients were usually under two years of age, though the disease occurred not infrequently later in life. A family history of tuberculosis could frequently be obtained. The onset was an insidious one of two weeks or longer of apathy, crying restlessness, occasional vomiting and fever; in younger children there might be convulsions. The condition of apathy, stupor and impaired mentality was a very striking one. During the greater part of their illness the children lay stupid, expressionless and respond slowly and indifferently to external stimulation. The same condition existed in adults. There were also signs of internal hydrocephalus, with the resulting Macewen in older children, or marked fontanelle bulging in younger ones. Local palsies were more common in tuberculous meningitis than in the other forms. The transitory nature of the palsies was especially striking. Vasomotor changes and marked tache were quite common. There was considerable irregularity of the pulse. Rigidity of the neck and Kernig were only moderate as a rule. The reflexes were irregular and at the onset of the disease usually exaggerated. Later in the course of the disease they were diminished or absent. In the early stages of the attack the temperature was only moderate, but later it ranged up to 104° or 105° F., and might show the marked intermittency of the cerebrospinal form. Tuberculous meningitis usually ran a short course, terminating in death in from two to four weeks after definite symptoms appeared. Epidemic cerebrospinal meningitis also had a definite and distinct symptom complex. The children averaged older; the onset was more acute, with rigors, high temperature, prostration and severe projectile vomiting. The patient was apt to be hypersensitive, irritable and constantly crying. Mentality, while usually flighty and disturbed by periods of delirium, was often, except in the last stages, entirely unimpaired for hours. Retraction of the head, tenderness in the back of the neck and Kernig's sign were marked. Reflexes were irregular and palsies were often entirely absent. Bulging fontanelle or Macewen were usually marked, but often to a lesser degree than in the tuberculous form. The pulse and respiration changes were not as marked, except in cases with marked hydrocephalus. Petechiæ and herpes were frequently seen. Cerebral temperatures of 106 or over were not unusual in this form of meningitis. These two forms of meningitis, while frequently easy to differentiate, sometimes so closely resembled one another as to make it impossible to make a clinical differential diagnosis. The other acute forms of meningitis, as streptococcus pyogenes, streptococcus mucosus capsulates, pneumococcus and influenza, presented almost the same symptom complex as epidemic meningitis. The history of previous disease, as otitis media, might be of some help, but the diagnosis could only be definitely established by lumbar puncture and examination of the cerebrospinal fluid. It was important to note that in pneumococcus meningitis

the cerebrospinal fluid might be sterile, due to a localized cortical meningitis. Meningitis complicating other acute infections while sometimes difficult to differentiate from epidemic meningitis could, as a rule, be diagnosed. One had first to establish the presence of the primary infection. The mental symptoms of restlessness and irritability were not accompanied by the anxiety, constant crying and complaining that accompanied the usual epidemic meningitis. Unless delirium was present the patient was usually bright and intelligent. Rigidity of the neck was only moderate and could often be relaxed. Kernig's and Macewen's signs were present to a lesser degree or might be absent. With the subsidence of the temperature and the disappearance of the original infection, the meningeal symptoms disappeared. Poliomyelitis often resembled tuberculous meningitis clinically, but the local palsies were extensive and permanent. Convulsions were frequent. The diagnosis might be suspected during the acute stage, but could only be absolutely established by lumbar puncture. The blood count was of some aid in diagnosis. The pricipal features were the high leucocytosis of 20,000 or more in the cerebrospinal form with the high relative polynucleosis, up to 99 per cent. In tuberculous meningitis there was moderate leucocytosis, up to 18,000, with a moderate relative polynucleosis up to 80 per cent. Poliomyelitis and polioencephalitis in the febrile stage showed a slight leucocytosis. The von Pirquet test was not done in this series of cases; however, it seemed to be of value at least in the negative result. Once a clinical diagnosis was made, whatever the form, lumbar puncture should be performed. Dr. Sophian presented another table showing the character of cerebrospinal fluids in the different types of infection. As a rule the study of the cerebrospinal fluid would, in the case of acute suppurating meningitis, enable one at the first examination to find the infecting organism. The unusual exceptions were rarely in the very onset of epidemic cerebrospinal meningitis, before the organism was free in the cerebrospinal fluid, or in localized meningitis, as the localized pneumococcus meningitis. It was important where a positive culture was desired to subinoculate the sediment on suitable culture media as soon as possible after withdrawal from the canal. The usual media used for this purpose were 2 per cent. glucose serum agar, blood agar and 2 per cent. glucose serum bouillon. In tuberculous meningitis the bacilli could usually be found in the cerebrospinal fluid, but it sometimes took a search of several hours. Cytological examination was exceedingly important. The increase in the number of cells was constant; in the suppurative forms the preponderance of polynuclear leucocytes was striking; in the late stages of cerebrospinal meningitis a relative leucocytosis was present. In the tuberculous form the excess of lymphocytes (up to 100 per cent.) was marked. An attempt to classify any particular type of meningitis merely on the number of cells, without the demonstration of the infecting organism, would apparently be an uncertain thing to do. The author spoke of the gross fibrin content of the fluid after standing as a fairly constant guide and referred to several other gross methods. He spoke briefly of the treatment that had been carried on along the lines laid down by Flexner. In the administration of the serum he urged the importance of a careful study of the condition of the patient as an indication for the use of serum and for varying the dose and for the purpose of recognizing early any complications such as basic meningitis with closure of the foramen.

Dr. Sophian also read a communication from Dr. Park stating that the Rockefeller Institute for Medical Research had turned over two horses which produced antimeningitis serum to the Department of Health, and that this serum would be supplied to physicians and when possible would be administered at their request. It was desirable that fluid from the spinal canal be obtained from all cases for bacteriological examination. The Department would gladly examine these specimens and would not refuse serum to those who found it impossible to obtain specimens of the fluid. At present there would be no charge in Greater New York for either the serum or the examinations.

Dr. William H. Park said that he wished to call attention to one aspect of the paper. All were trying to find the exciting factor in these cases of meningitis. Very favorable findings were coming from the laboratories; Dr. Hemenway had found in forty consecutive cases that the majority of them were due to the meningococcus and not to the tubercle bacillus. This was very interesting, and he hoped that the information that was so earnestly sought would soon be collected. The Health Department was working to bring about the best results.

Dr. Henry Koplik brought out a few clinical points of value in making a diagnosis of meningitis from other conditions. During an epidemic of poliomyelitis it was a simple matter for an experienced man to recognize the disease; but when there was no epidemic he did not know of any disease more difficult to diagnose. In the cases referred to it was a mistake to make such hopeless prognoses; many of these patients were perfectly well in four or five weeks. In making a diagnosis one should inquire very carefully into the mode of onset. If one could get an absolutely reliable history of an acute onset, tuberculous meningitis could be excluded. This point could not be sufficiently emphasized. The clinical signs should be carefully looked into and the case thoroughly studied before a positive diagnosis was made. The point regarding cytology as giving diagnostic evidence he did not think was well taken. If one found microorganisms of the disease, all right. He thought that Dr. Sophian and Dr. Hemenway had done very painstaking work, and hoped that they might soon give them a method by which the finding of the tubercle bacilli could be made more easy.

Dr. William P. Northrup said that the American Pediatric Society had offered a prize to the person who would give it four of the best diagnostic symptoms of the disease under discussion; nothing came of it. Tuberculosis of the choroid had been described; he had been looking for such a condition for twelve years and had not been able to demonstrate it post mortem.

Dr. Henry Heiman said that a diagnosis should be made by exclusion. The parents should be informed of the value of lumbar puncture. With regard to the cytology; if they found 100 per cent. of lymphocytes there then was a possibility that they were dealing with tuberculous meningitis. In the pyogenic form of meningitis the time should be taken into consideration; if the patient had been ill but a week or ten days a diagnosis of pyogenic meningitis should be made; if the patient had been ill beyond this time a diagnosis of cerebrospinal meningitis should be made.

Dr. Charles E. Nammack recalled Dr. Hemenway's report at a recent meeting in which the tubercle bacillus was recognized 135 times in a series of 138 cases of meningitis; this showed very good laboratory work.

Dr. Sidney V. Haas referred to a case of acute intestinal intoxication which gave rise to the classical symptoms of acute meningitis, a condition which was more common than was generally supposed. At the Lebanon Hospital four cases had recently been sent in with the diagnosis of cerebrospinal meningitis which were found to be cases of intestinal intoxication. Examination should be made for acetone and diacetic acid in the urine. Many years ago he had had a case of tuberculosis of the choroid demonstrated to him.

Dr. Abraham Sophian said, in closing the discussion, that in many cases lumbar puncture was a necessity.

The Subsequent Health of Children Who Drank Milk Containing Tubercle Bacilli.—Dr. Alfred Fabian Hess said that three years ago he made a report on the examination of the milk of the City of New York as regards the frequency with which it contained tubercle bacilli. He found that of 107 specimens examined 17 contained virulent bacilli; that was to say, 16 per cent. He found, however, that the children who drank this milk were at that time in no definite way affected. He now reported upon the further health of these children, having very carefully observed them for this period. These children, 18 in number, it should be noted, drank milk in which tubercle bacilli were found, and may have drunk it at different times, but certainly were not exposed to this infection subsequent to this time, as the mothers were warned to boil the milk after this danger was passed. Dr. Hess said of these 18 children one had developed tuberculosis of the cervical glands from which he cultivated a bacillus which proved to be of the bovine type as tested by its virulence for rabbits and its cultural growth. The other 17 children were of about average health and did not show any bad effects from their exposure. At the time they drank the milk almost all of them were below two years of age. Dr. Hess brought out another interesting point as the result of experiments on guinea-pigs; this was the frequency of infection as well as the dose of bacilli. He showed that, although these animals could not be affected by taking two milligrams of tubercle bacilli in milk by mouth, when the material was given in one dose, they could be infected with less than this amount if it was divided into 10, 20 or 30 doses given upon as many days. He reasoned by analogy that it made a difference whether children took a small amount of tubercle bacilli in one dose or on successive days. Another point Dr. Hess brought out was the necessity of providing a safe butter. It was striking that they were afraid to give children milk containing tubercle bacilli, but that they were not afraid to give children, between the ages of one and two years, butter containing large numbers of these organisms. There should be a means for providing a safe butter just as there was now a way of obtaining a safe milk. It would seem practical if through the efforts of the certified milk commissions they were enabled to purchase a certified or a Pasteurized butter; at any rate this was a timely subject for consideration by those commissions who had effected such excellent results as regards the milk supply.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Pennsylvania State Board of Medical Examiners.

June, 1911.

ANATOMY.

1. Describe the shoulder joint.
2. Describe the appendix vermiformis and give its relations.
3. Describe the prostate gland and give its relations.
4. Name the structures within the female pelvis and give their relations.
5. Describe the "anatomy" involved in an operation for the radical cure of oblique inguinal hernia.
6. Describe the tibia and give in detail its articulations.
7. Describe the fascia lata and give its regional anatomy.
8. Describe the female perineum and the relations of its muscles and fasciæ.
9. Describe the gross anatomy of the stomach and give its relations.
10. Describe the distribution of the peritoneum.

PHYSIOLOGY.

1. Describe three functions of adipose tissue.
2. Describe the functions of the Haversian canals.
3. What changes take place in the circulation after the ligation of an artery?
4. Describe the mechanism of vision.
5. State the functions respectively of the renal glomerular and tubular epithelium.

PATHOLOGY.

1. Describe the physical changes characterizing lesions of the cardiac valves and the effects of such changes upon the "sounds of the heart."
2. Define: Hyperemia, hypertrophy, hyperplasia and hypoplasia.
3. Give a brief outline of the pathologic changes that occur in the various types of peritonitis.
4. Name the immediate and remote pathologic conditions that may result from gonococcus infection.
5. Describe the renal changes occurring in cirrhotic kidney.

PRACTICE AND THERAPEUTICS.

1. What are the symptoms and signs of acute dilatation of the heart?
2. Describe the symptoms of intestinal perforation in typhoid fever.
3. What are the symptoms and characteristic course of a case of erysipelas?
4. How would you treat a case of suppression of urine due to acute Bright's disease?
5. What are the symptoms and treatment of poisoning by chloral hydrate?
6. Outline the dietetic, medicinal, and hygienic management of a case of typhoid fever.
7. Describe the prophylactic and curative treatment of a case of ophthalmia neonatorum.
8. How would you treat a case of ivy (rhus toxicodendron) poisoning?
9. Outline symptoms and course of a case of tabes dorsalis (locomotor ataxia).
10. What are the characteristic features of a case of psoriasis?

SURGERY.

1. Give the symptoms of and describe an operation for the correction of movable kidney.
2. Describe the indications and the technic for paracentesis of the membrana tympani.
3. Describe in detail two methods for the reduction of a dislocation of the shoulder joint.
4. Describe three methods for the radical cure of hemorroids with reasons for the employment of each method.
5. Give the more common symptoms of chronic appendicitis and state the symptoms that indicate extreme urgency for operation.
6. Outline the surgical treatment of gunshot wounds of the abdomen.
7. Describe in detail the application of two methods of the non-operative treatment of epithelioma of the skin.
8. Describe the surgical treatment of the various types of stricture in the male urethra.
9. Give the symptoms requiring curetage of the uterus and describe in detail the technic of the operation.
10. Name the complication that may arise from undescended testes and describe an operation for its correction.

OBSTETRICS.

1. Describe methods to determine the position of the fetus previous to labor.
2. State the normal pelvic measurements and describe the methods of determining the same.
3. State the dangers to the cord in the various stages of labor and describe the methods of overcoming these dangers.
4. For what conditions and at what period of time should cesarean section be performed?
5. Describe the proper attention to a newly born babe.
6. Describe the proper preparation of the lying-in room and bed.
7. Name four causes of dystocia, with the treatment of any one form.
8. Describe the delivery in a case of breech presentation requiring the application of forceps.
9. Define involution. State causes of delayed involution and subinvolution.
10. Give management of a case with occiput in the hollow of the sacrum.

CHEMISTRY.

1. Describe a test for the detection of free hydrochloric acid in the gastric contents.
2. Describe a chemical test respectively for chlorids, urates, earthly phosphates.
3. How can the presence of sewage in water be chemically detected?
4. When testing for glycosuria with a copper solution,

how do you determine whether the reaction is that of "sugar" or of some other reducing agent?

5. Give a chemical test for the presence of indican in the urine.

MATERIA MEDICA.

1. (*a*) Give the official title of digitalis. (*b*) Give the names and doses of its preparations.

2. What are the doses of the following drugs? (*a*) Codeinæ sulphas. (*b*) Atropiæ sulphas. (*c*) Hyoscin hydrobromidum. (*d*) Cocain hydrochloricum.

3. Name the preparations of ergot. Give the dose of each.

4. Give an example of an official preparation belonging to the following classes: (*a*) Tonics. (*b*) Stimulants. (*c*) Emetics. (*d*) Astringents.

5. Name two alkaloids obtained from each of the following drugs: (*a*) Nux vomica. (*b*) Cinchona. (*c*) Opium.

DIAGNOSIS.

1. Differentiate infantile scurvy and infantile rheumatism.

2. Differentiate apoplexy from conditions that simulate it.

3. Differentiate duodenal ulcer from conditions that simulate it.

4. Differentiate appendicitis, cholecystitis, salpingitis, and intestinal obstruction.

5. Diagnosticate iritis.

HYGIENE.

1. Give dietetic and hygienic treatment of "scarlet fever."

2. Outline dietetic and hygienic care in acute nephritis.

3. Name two of the most infectious and contagious diseases contracted in schools, and state how you would endeavor to prevent them.

4. What are the most frequent defects of vision in school children? What care and treatment should they receive?

5. Outline hygienic and dietetic care of pulmonary tuberculosis.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

PENNSYLVANIA STATE BOARD OF MEDICAL EXAMINERS.

June, 1911.

ANATOMY.

1. See Cunningham's "Anatomy" (1909), page 276; or Gray's "Anatomy" (1910), page 301.

2. See Cunningham's "Anatomy" (1909), page 1079; or Gray's "Anatomy" (1910), page 1299.

3. See Cunningham's "Anatomy" (1909), page 1173; or Gray's "Anatomy" (1910), page 1393.

RELATIONS OF PROSTATE. *Anteriorly:* Symphysis pubis, anterior ligaments of bladder, branches of dorsal vein of penis. *Posteriorly:* Rectum. *Laterally:* Levator ani. *Base:* Surrounds neck of bladder, seminal vesicles, and vasa deferentia. The *apex* rests on triangular ligament.

4. Ureters, bladder, part of the small intestine, rectum, uterus, ovaries, Fallopian tubes, vagina.

5. See Rose and Carless' "Surgery" (1908), page 1073; or Da Costa's "Surgery" (1908), pages 909 and 978.

6. See Cunningham's "Anatomy" (1909), pages 231, 297, 304, and 306; or Gray's "Anatomy" (1910), pages 231, 331, 360, and 342.

7. See Cunningham's "Anatomy" (1909), page 353; or Gray's "Anatomy" (1910), page 507.

8. See Gray's "Anatomy" (1910), page 445.

9. STOMACH is conical, with base to left side; the upper border is concave, and is called the *lesser* curvature; the lower border is convex, and is named the *greater* curvature. The left extremity is known as the *fundus;* above and to the right of which is the *cardiac* orifice, and the right or small end is termed the *pyloric* extremity. It occupies left hypochondriac and epigastric regions. Its *orifices are cardiac*, above, communicating with the esophagus; *pyloric*, at the right extremity, passing into the duodenum. It is 10 to 12 inches long, 4 to 5 inches in diameter at widest part. Its *left* or *cardiac end* is fixed by esophagus and gastrophrenic ligament to diaphragm, lying beneath the seventh left costal cartilage, 1 inch from sternum; it is connected with the spleen by the gastrosplenic omentum. The *right* or *pyloric end* reaches the gall-bladder, touching under part of quadrate lobe of liver; is very movable; when stomach is empty is in midline 4 inches below tip of gladiolus. *Anterior surface*, which also looks upward, is in contact with, from left to right, diaphragm, abdominal parietes (epigastric region), under surface of liver. *Posterior surface* is separated from pancreas, crura of diaphragm, aorta, vena cava inferior, and solar plexus, by lesser sac of peritoneum. *Superior border* is attached to liver by small omentum. *Inferior border* gives attachment to great omentum. *Coronary* and *pyloric* arteries run along lesser curvature; *right* and *left gastroepiploic*, along inferior or greater curvature; *vasa brevia*, from the splenic to fundus. *Right pneumogastric* nerve supplies to posterior surface; *left pneumogastric*, the anterior surface; *sympathetic*, from the solar plexus, both surfaces.—(*Aids to Anatomy.*)

10. See Cunningham's "Anatomy" (1909), page 1048; or Gray's "Anatomy" (1910), page 1244.

PHYSIOLOGY.

1. *Three functions of adipose tissue:* (1) It is a reserve store of food; (2) protection of delicate structures; (3) it preserves the heat of the body.

2. *The Haversian canals* serve to conduct arteries, veins, lymphatics, and nerves to and from the bone substance.

3. After ligation of an artery the inner and middle coats curl up and retract, a small thrombus forms, which later on is replaced by fibrous tissue. The vessel is thus obliterated and a new or collateral circulation is established. The ligature of a large artery is followed by a rise in the general blood-pressure, which decreases as the collateral circulation is established.

4.

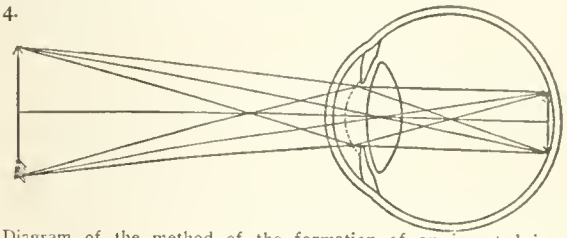

Diagram of the method of the formation of an inverted image exactly focused upon the Retina. The dotted line is the ideal surface of curvature.

5. The *glomerular epithelium* of the kidney is responsible for the fluid and inorganic salts of the urine; the *tubular epithelium* for the urea, uric acid, and principal solids.

PATHOLOGY.

1. See French's "Practice of Medicine" (1910), pages 584, 586, 594, 598, 603, etc.; or Osler's "Practice of Medicine" (1909), pages 792, 793, 797, 802, 808, etc.

2. *Hyperemia* is a condition characterized by excess of blood in a part. *Hypertrophy* is "an increase in the size, weight, and functional activity of a part beyond the limit of health, due to an orderly enlargement or multiplication of all its normal constituents."

Hyperplasia is a numerical hypertrophy; that is, an hypertrophy in which there is a numerical increase in the cells of the part.

Hypoplasia is a condition in which there is atrophy of a part due to the destruction of some of its cells.

3. See French's "Practice of Medicine" (1910), pages 882 and 887; or Osler's "Practice of Medicine" (1909), pages 581, 584, and 586.

4. See French's "Practice of Medicine" (1910), pages 215 and 216; or Osler's "Practice of Medicine" (1909), page 282.

5. See French's "Practice of Medicine" (1910), page 925; or Osler's "Practice of Medicine" (1909), page 695.

PRACTICE AND THERAPEUTICS.

1. See French's "Practice of Medicine" (1910), page 617; or Osler's "Practice of Medicine" (1909), page 820.

2. See French's "Practice of Medicine" (1910), page 87; or Osler's "Practice of Medicine" (1909), page 82.

3. See French's "Practice of Medicine" (1910), page 219; or Osler's "Practice of Medicine" (1909), page 211.

4. See French's "Practice of Medicine" (1910), pages 897 and 915; or Osler's "Practice of Medicine" (1909), pages 669 and 690.

5. POISONING BY CHLORAL HYDRATE. *Symptoms:* Deep sleep, with the vessels of the head and neck greatly congested, accelerated pulse, widely dilated pupils, and deep though irregular respiration. Later the face becomes blanched and livid, the pupils contracted, the circulation and respiration fail, and the temperature falls. In some cases death occurs in from one-quarter to one hour in a condition of collapse. The usual fatal period is 8 to 10 hours.

Treatment: Stomach tube. Artificial respiration, flagellation, faradism. No chemical antidote is known. (Witthaus' *Essentials of Chemistry.*)

6. See French's "Practice of Medicine" (1910), pages 107, etc.; or Osler's "Practice of Medicine" (1909), pages 96, etc.

7. Ophthalmia neonatorm. *Propyhlaxis:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth. *Treatment:* Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burned.

8. *Treatment of ivy poisoning:* "Sedative lotions are most efficacious in subduing the inflammation. One of the most soothing is a saturated aqueous solution of boric acid containing ten minims of glycerin to the ounce. Sodium hyposulphite solution (5i to the ounce), dilute fluid extract of grindelia robusta (5i to 4 ounces of water), and lotio nigra and lime-water are also very beneficial. The itching may be relieved by the addition of carbolic acid (10 minims to the ounce) and glycerin (10 minims) to any of the preparations. The great danger lies in overtreating, in an effort to allay the itching and burning." (Hughes' *Practice of Medicine.*)

9. See French's "Practice of Medicine" (1910), page 1082; or Osler's "Practice of Medicine" (1909), page 889.

10. "*Psoriasis* begins as small, reddish spots of the size of a pin's head, which immediately become covered with scanty or abundant whitish or grayish imbricated scales. The spots gradually increase in diameter by peripheral extension, forming patches of various sizes and shapes. If an attempt be made to detach one of the scales by means of the finger-nail, it will be found to adhere quite firmly to the skin, and to be about the thickness of a cardboard. If the reddish patch thus made bare be pinched up between the finger and thumb, and compared with a similar pinch of the healthy skin, its inflammatory thickening will be discerned. A punctate hemorrhage often follows removal of the scales by scratching. *There is no watery discharge at any time.* The skin between the patches is perfectly healthy. Any portion of the body is liable to be attacked with psoriasis, but the elbows, knees, and scalp are involved with greatest frequency. The only discomfort the patient suffers is from the itching, which at times is very severe and distressing. The disease is essentially chronic. Few cases become permanently cured, but the affection shows spontaneous improvement in the summer months in many cases. The eruption may partially or completely disappear with or without treatment, but recurrence is to be expected." (Hughes' *Practice of Medicine.*)

SURGERY.

1. See Rose and Carless' "Surgery" (1908), pages 1160 and 1161; or Da Costa's "Surgery" (1908), pages 1103 and 1105.

2. *Indications* for paracentesis of the membrana tympani: In some cases of otitis media, for drainage, to deplete the parts, or for exploratory purposes. And see Roseand Carless' "Surgery" (1908), page 882.

3. See Rose and Carless' "Surgery" (1908), page 622; or Da Costa's "Surgery" (1908), page 590.

4. See Rose and Carless' "Surgery" (1908), page 1152; or Da Costa's "Surgery" (1908), page 1015.

5. See Rose and Carless' "Surgery" (1908), pages 1041, 1044, and 1049; or Da Costa's "Surgery" (1908), pages 853 and 863.

6. See Rose and Carless' "Surgery" (1908), page 244; or Da Costa's "Surgery" (1908), page 821.

7. See Rose and Carless' "Surgery" (1908), page 217.

8. See Rose and Carless' "Surgery" (1908), page 1241; or Da Costa's "Surgery" (1908), page 1172.

9. *Curettage is indicated:* (1) For removal of placental débris (2) in hemorrhagic endometritis, (3) in some forms of dysmenorrhea (membranous), (4) for diagnostic purposes, (5) in some cases of puerperal sepsis, (6) sometimes to check hemorrhage, due to fibroids. *Contraindications:* (1) The least suspicion of even the possibility of pregnancy; (2) menstruation; (3) acute endometritis; (4) malignant disease of the uterus or vagina; (4) acute pelvic inflammation.

Technique: All antiseptic and aseptic precautions are necessary, the patient should be in the dorsal position, the vagina is to be disinfected, and the cervical canal dilated; a speculum is introduced into the vagina and the cervix is drawn down with volsella; the uterine cavity is irrigated with creolin or lysol; a curette is inserted to the fundus and moved down to the internal os; the operator should begin at one cornu and go in the same direction all around till he reaches the starting point, and if necessary repeat till no more spongy or hyperplastic tissue appears; the fundus should be scraped separately by moving the curette along it from side to side; in going toward the fundus no scraping should be done, and care must be taken not to perforate the uterus; should this happen no fluid must be injected; otherwise the uterus and vagina are again irritated, and one or more strips of iodoform gauze are inserted into the cavity to act either as a hemostatic plug or as a drain, which is diminished with two days' interval and withdrawn on the sixth day. A hemostatic tampon should be placed in the vagina and withdrawn the following day. If any fever arises, the tampon is at once removed and the vagina douched with antiseptic fluid every three hours. If not, the vagina is only swabbed with the same every day, and packed loosely with iodoform gauze. After the final removal of the gauze the antiseptic douche is given twice a day until there is no more discharge. The patient should remain in bed for a week.

10. See Rose and Carless' "Surgery" (1908), pages 1253 and 1254; or Da Costa's "Surgery" (1908), page 1198.

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), page 211; or Hirst's "Obstetrics" (1909), pages 389 and 390.

2. See Williams' "Obstetrics" (1909), pages 4 and 683; or Hirst's "Obstetrics" (1909), pages 22 and 448.

3. See Williams' "Obstetrics" (1909), pages 319, 289, 598, 597, 397, and 586; or Hirst's "Obstetrics" (1909), pages 141, 138, 625, 627, and 570.

4. See Williams' "Obstetrics" (1909), page 443; or Hirst's "Obstetrics" (1909), page 857.

5. See Williams' "Obstetrics" (1909), page 347; or Hirst's "Obstetrics" (1909), page 928.

6. See Williams' "Obstetrics" (1909), pages 303 and 312; or Hirst's "Obstetrics" (1909), page 329.

7. *Four causes of dystocia:* Deformed pelvis; tumors of the pelvis or of the genital canal; rigidity of os uteri; and hydrocephalus. For treatment of hydrocephalus, see Williams' "Obstetrics" (1909), pages 795 and 465; or Hirst's "Obstetrics" (1909), page 561.

8. See Williams' "Obstetrics" (1909), pages 419, 429, and 432; or Hirst's "Obstetrics" (1909), page 826.

9. See Williams' "Obstetrics" (1909), pages 332 and 904; or Hirst's "Obstetrics" (1909), pages 348, 367 and 645.

10. See Williams' "Obstetrics" (1909), page 268; or Hirst's "Obstetrics" (1909), pages 407 and 821.

CHEMISTRY.

1. *Test for free hydrochloric acid in gastric contents:* Gunzburg's reagent (phloroglucin 2 grams; vanillin, 1 gram; dissolved in 100 cc. of alchohol) freshly prepared, and a few drops of filtered gastric contents (equal parts of each) are mixed in a porcelain dish, and then evaporated in a water bath; in the presence of free mineral acids a bright scarlet is produced, beginning at the upper border.

2. *Test for chlorides:* Addition of silver nitrate gives a white flocculent precipitate which is insoluble in nitric acid, but soluble in ammonium hydroxide.

Test for urates: Addition of dilute nitric acid followed by evaporation to dryness leaves a yellowish-red residue. Then add a little ammonia, and the residue turns to violet.

Test for earthy phosphates: Addition of ammonia causes a white precipitate, which becomes more apparent on standing.

3. The presence of sewage in water can be chemically detected by adding a solution of permanganate of potassium; in the presence of sewage rapid decoloration occurs.

4. By making a confirmatory test by the fermentation method; this latter is only positive with "sugar."

5. *Test for indican in the urine:* The urine is mixed with one-fifth its volume of 20 per cent. solution of lead acetate and filtered. The filtrate is mixed with an equal volume of fuming hydrochloric acid containing 3:1000 of ferric chloride, a few drops of chloroform are added, and the mixture strongly shaken one to two minutes. With normal urine the chloroform remains colorless, or almost so; but if an excess of indoxyl compounds be present the chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess.

MATERIA MEDICA.

1. Digitalis. *Official title:* Digitalis. *Preparations and Doses:* Fluidextract, ♏j; extract, gr. 1-5; infusion, 5ij; tincture, ♏xv.

2. Dose of codeine sulphate, gr. ½; of atropine sulphate, gr. 1-160; of hyoscyin hydrobromide, gr. 1-128; of cocaine hydrochloride, gr. ½.

3. The official preparations of ergot and their doses are: Ergot, thirty grains; extract of ergot, seven and a half grains; fluidextract of ergot, thirty minims; wine of ergot, two drams.

4. *Tonic:* Tincture of ferric chloride. *Stimulant:* Ammonia water. *Emetic:* Apomorphine hydrochloride. *Astringent:* Alum.

5. Two alkaloids, *of Nux Vomica:* Strychnine and brucine; of *Cinchona:* Quinine and cinchonine; of *Opium:* Morphine and codeine.

DIAGNOSIS.

1. Infantile rheumatism is extremely rare; pain and tenderness of the legs only should in an infant invariably suggest scurvy rather than rheumatism. In scurvy the extreme soreness of the legs, spongy swollen gums, swelling near the large joints, a tendency to hemorrhages, and a usual history of the prolonged use of some proprietary infant food or sterilized or condensed milk will be present. If any doubt exists this will be removed by the prompt improvement and generally rapid cure following an antiscorbutic diet. (From Holt's *Diseases of Infancy and Children.*)

2. The following table (from Sisendrath's *Surgical Diagnosis*) gives the diagnosis:

ACUTE IRITIS.	ACUTE CONJUNCTIVITIS.	ACUTE GLAUCOMA.
1. Pupil: small, sluggish, irregular after atropine.	Normal.	Dilated, oval, fixed.
2. Iris: swollen, dirty, lymph on surface.	Clean and bright.	Swollen and discolored.
3. Anterior chamber: normal (or deeper, with turbid contents).	Normal.	Shallow.
4. Cornea: clear (or with deposits on back).	Clear.	Steamy; *anesthetic.*
5. Ciliary region: injected.	Not injected.	Injected.
6. Conjunctiva: usually some injection.	Red, opaque, perhaps swollen.	Great congestion, perhaps chemosis.

COMA FROM INTRACRANIAL INJURY.	APOPLECTIC COMA.	UREMIC COMA.	ALCOHOLIC COMA.	OPIUM POISONING.
Deep coma; may have history of onset after fall or injury. Evidence of fracture of vertex or base.	Deep coma; sudden onset. If any injury, only a scalp wound.	Deep coma. Slow onset unless convulsions have preceded the coma.	Can be aroused by supraorbital pressure unless very profound.	Can be aroused unless very deep.
Pupil dilated on side of lesion. Choked disc.	Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Albuminuric retinitis.	Pupils normal or somewhat dilated.	Pupils contracted to pinpoint size.
Pulse very slow.	Pulse full and slow, often arteriosclerotic high-tension pulse.	Pulse rapid.	Pulse more rapid than normal and full.	Pulse rapid, may be irregular.
Respiration slow and stertorous.	Respiration slow and irregular.	Respiration frequent and irregular.	Regular respiration.	Respiration very slow—may be 6 to 8 per minute.
Temperature higher—101°.	Temperature higher on paralyzed side, but lower in rectum.		May be low or normal.	
Urine normal or contains trace of albumin.	Urine contains trace of albumin, but may be same as in uremia.	Urine shows albumin, casts, and low urea percentage.	Normal.	Normal.
Hemiplegia on opposite side to that of injury. If contusion of brain is also present, may have generalized convulsions.	Hemiplegia with convulsions on one side.			

3. See French's "Practice of Medicine" (1910), page 767; or "Osler's "Practice of Medicine" (1909), page 476.

4. See French's "Practice of Medicine" (1910), page 813; or Osler's "Practice of Medicine" (1909), page 517.

ACUTE APPENDICITIS.	ACUTE SALPINGITIS.
1. Muscular rigidity marked.	1. But little rigidity.
2. Pain begins at umbilicus and becomes localized over McBurney's point unless appendix points to pelvis.	2. Pain lower down in abdomen just above Poupart's ligament.
3. Tenderness over right iliac fossa.	3. Tenderness low down over pelvis.
4. Pain followed in a few hours by nausea and vomiting.	4. Nausea and vomiting infrequent.
5. Bimanual examination negative unless appendix in pelvis, then tenderness lateral to uterus.	5. Bimanual examination shows tender mass lateral to or behind uterus.
6. No history of gonorrheal infection	6. Usually history of infection to be obtained.

When acute appendicitis occurs during the course of an acute inflammation of the female pelvic organs a differentiation is impossible, except that the pain is most intense over McBurney's point.—(Eisendrath.)

5.

ACUTE IRITIS.	ACUTE CONJUNCTIVITIS.	ACUTE GLAUCOMA.
7. Discharge: tears only.	Mucopus.	Tears only.
8. Palpation: tension normal (occasionally + 1); tender in ciliary region.	Tension normal, not tender.	Tension + 2 to 3, very tender.
9. Pain: over forehead and nose, worse at night.	Sand or grit in eyes.	Intense neuralgia in and about eyes, nausea, vomiting.
10. Vision: clouded.	Scarcely affected.	Rapidly lost; field extremely limited; "rainbow rings" seen.
11. Disc: if seen, normal.	Normal.	If seen, cupped, and arterial pulsation.

HYGIENE.

1. See French's "Practice of Medicine" (1910), page 324; or Osler's "Practice of Medicine" (1909), page 138.

2. See French's "Practice of Medicine" (1910), page 915; or Osler's "Practice of Medicine" (1909), page 690.

3. Scarlet fever and measles. See French's "Practice of Medicine" (1910), pages 324 and 330; or Osler's "Practice of Medicine" (1909), pages 138 and 144.

The principal means of preventing the spread of contagious diseases in schools are: Regular and efficient inspection by physicians; prompt exclusion and isolation of anyone suffering from a contagious disease, or coming from a house where such disease is; compulsory notification of all infectious and contagious disease; individual towels, drinking vessels, and other implements; children who have had a contagious or infectious disease or who have come from a house where such disease prevailed should not be readmitted to school until sufficient time has elapsed since the occurrence of the last case to insure safety.

4. Myopia, hypermetropia, and astigmatism are the most frequent defects of vision in school children. The school authorities should provide books with proper paper and print, suitable illumination, desks of proper height; proper positions in reading and writing should be enforced; the children should not use their eyes when tired; excessive study should be forbidden. The child's eyes should be examined and glasses provided by a competent physician.

5. See French's "Practice of Medicine" (1910), page 399; or Osler's "Practice of Medicine" (1909), pages 353 and 356.

BULLETIN OF APPROACHING EXAMINATIONS.

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 9
Arizona*	Ancil Martin, Phoenix	Phoenix	Jan. 2
Arkansas	F. T. Murphy, Brinkley	Little Rock	Nov. 14
California*	Chas. L. Tisdale, 929 Butler Building, San Francisco	Los Angeles	Dec. 5
Colorado	David A. Strickler, Empire Building, Denver	Denver	Jan. 2
Connecticut*	Chas. A Tuttle, New Haven	New Haven	Nov. 14
Delaware	J. H. Wilson, Dover	Dover	Dec. 12
Dist. of Col'ba	Geo. C. Ober, Washington	Washington	Oct. 12
Florida*	I. D. Fernandez, Jacksonville	Jacksonville	Nov. 7
Georgia	C. T. Nolan, Marietta	Atlanta	Oct. 10
Idaho*	O. J. Allen, Bellevue	Wallace	April 2
Illinois	J. A. Egan, Springfield	Chicago	Oct. 26
Indiana	W. T. Gott, Crawfordsville	Indianapolis	Jan. 9
Iowa	G. H. Sumner, Des Moines	Des Moines	Sept. 19
Kansas	H. A. Dykes, Lebanon	Topeka	Oct. 10
Kentucky	J. N. McCormack, Bowling Green	Louisville	Dec. 19
Louisiana	A. B. Brown, Cusach's Bldg., New Orleans	New Orleans	Oct. 19

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Case of Trophic Ulceration over a Large Formation of Scar Tissue.—M. Corner reports the case of a patient who broke his patella for the first time twenty-four years ago, subsequently breaking it again twice. It was wired in 1896, but suppurated, necessitating removal of the patella, incision and irrigation. Without any ascertainable cause nine months ago the scar began to ulcerate in its center and was slow to respond to treatment.—*Proceedings of the Royal Society of Medicine.*

Medicolegal Notes.

Expert Evidence Admissible to Show That Homicide Could Not Have Been Suicidal.—In a prosecution for murder the throat of the deceased was found to have been slashed in front with some sharp instrument which passed through almost to the spinal column, completely severing the gullet and jugular vein. It was undisputed that the deceased was left-handed, and to rebut any possible inference that the homicide was suicidal the medical examiners who conducted the autopsy and a physician who viewed the body and heard their testimony of the details, and whose qualifications were unquestioned, were called by the government and permitted to testify that, from the character, depth, and direction of the wounds, they could not have been self inflicted. This was objected to by the defense as opinion evidence, but the objection was not sustained. While the value of such evidence must differ in degree according to the nature of the inquiry, yet in the department of medicine and surgery such testimony often is of much importance, and a wide range of inquiry is usually permitted. The medical experts from their attainments in anatomy, united with the experimental knowledge acquired from study and observation of the effect of blows or wounds upon the human body, were peculiarly well fitted to express an opinion whether the left hand and arm of the deceased could have been so moved as to have been sufficient in scope and power to have produced a blow causing a wound of the severity and dimensions found on the deceased.—Commonwealth v. Spiropoulos, Massachusetts Supreme Court, 94 N. E. 451.

Chiropractic "Adjustment" Is Treatment.—On a trial for practising medicine without a license by a mode of treatment of the sick known as chiropractic the defendant testified that instead of using "treatments" she used "adjustments," and hence was not guilty of any violation of the statute. It was held that the methods used by the defendant fell as well within the definition of "treatment" as they did of "adjustment." She had the patient remove her street clothing and put on a kimono; she diagnosed her ailments with the aid of a vibrator; she manually manipulated the supposedly diseased parts; she described a dietary for the patient; she collected a fee, and advised the patient to return for further manipulation. The fact that the act regulating the practice of medicine contains provisions affecting a variety of practitioners having different methods of treating the sick was held not to render it subject to the objection that it contains more than one subject. Although called chiropractic, if the practice had any beneficial purpose at all its purpose was to heal the sick and afflicted, and to regulate the practice of healing the sick and afflicted is unquestionably within the acknowledged powers of the State.—State v. Grecnei, Washington Supreme Court, 114 Pac. 897.

Chiropractic Must Be Licensed.—Iowa Code, Section 2579, 2580, defining those practising as physicians as those publicly professing to be physicians and assuming the duties, or as those making a practice of prescribing medicine for the sick, or as those who publicly profess to heal or cure, and imposing a penalty on any one who, without a license, by his conduct brings himself within any of the enumerated classes, enumerates several acts disjunctively which may constitute the offense of practising medicine without a license, and the different acts constituting the offense are not necessarily inconsistent with each other. An indictment charging the accused as within all the classes therefore charges only one offense. An indictment charging the accused with wilfully assuming the duties of a physician and making a practice of treating persons afflicted with disease, and wilfully professing to cure persons afflicted with disease by a system of treatment called chiropractic, without having obtained a license, is, in substance, in the language of the statute, and sufficient. It was held that one advertising himself as a chiropractic and undertaking to heal persons according to that system by manipulating the spine of the patient practises as a physician within Code § 2579. The State has power to determine what acts constitute practice as a physician and may impose conditions on the exercise of that privilege. A statute providing that one practising as a physician shall possess some knowledge of the nature of disease, its origin, anatomical and physiological features, and its causative relation, and of the preparation and action of drugs is not unreasonable.—State v. Corwin, Iowa Supreme Court, 131 N. W. 659.

Standard of Degree of Care in Childbirth Case.—In an action for compensation for medical services rendered in the delivery of the defendant's wife, the defendant counterclaimed for damages for malpractice. The jury

found for the plaintiff and on appeal the evidence was held to sustain this verdict. The dependant's testimony was to the effect that the plaintiff used defective instruments, forceps tied together after they were adjusted on the head of the infant with a string, say, a piece of silk, with the result that the fastening broke and allowed the forceps to pull loose, causing a rupture of the parts, when if the forceps had been of the proper kind or properly fastened such result would not have followed. The evidence tended to show that the plaintiff used an amount of force and violence in attempting to extricate the infant from its mother's womb which was unnecessary and improper, resulting in unnecessary injuries to the patient, including rupture of the perineum and sphincter muscle, and also improper method of treatment after the rupture.

It was no defense for the plaintiff that he had knowledge and skill sufficient to practise his profession and erred merely in judgment in using instruments at the time and in the method of using these. If he was careless or did not use the judgment which a competent physician would ordinarily use under the circumstances of the case, then he was liable to damages. If he used such reasonable skill and diligence as were used by physicians in localities similar to that in which he practised, the Iowa court held that he was not liable for the outcome of the treatment. The plaintiff practised in a small country town in which the standard of medical practice appeared to be no higher than that of similar localities. Therefore an instruction that negligence was the doing of some act which under the circumstances would not be done by other average physicians of the vicinity in which the physician was practising, while erroneous in failing to measure his skill by that of those in similar localities, was not prejudicial to him.—Kline v. Nicholson, Iowa Supreme Court, 130 N. W. 722.

Statutory Meaning of Vaccination.—In an action by a parent to have it declared that he had a right to have his infant daughter attend public school the case turned upon the meaning of the term "vaccination" as used in the Pennsylvania act of June 18, 1895 (P. L. 207, § 12), prohibiting the attendance of a child at school without a certificate of successful vaccination, or of its having had the smallpox. It was held that the ordinary and usual meaning of "vaccination" and the sense in which it must be supposed to have been used by the Legislature is inoculation with the virus of cowpox, for the purpose of communicating that disease as a prophylactic against smallpox. It indicates an operation by inserting the virus under the skin, and the test of its success is the appearance of the symptoms of the disease, including those manifesting themselves on the skin. Administering the virus through the mouth, though producing practically the same symptoms on the body, except exterior and local inflammation, is insufficient.

It was also held that the act of April 27, 1905 (V. L. 315 § 10), giving the state health department authority to fix forms of certificates of vaccination required by the 1895 act, is not objectionable as a delegation of legislative power, but the department merely regulates the form of the certificate so as to require the certifying physician to use words in the sense in which they are used in the act of 1895.—Lee v. Marsh, Pennsylvania Supreme Court, 79 Atl. 564.

Action of Debt for Penalty for Practising Without a License Not a Prosecution.—Section of the Illinois act to regulate the practice of medicine within the State (Laws 1899, p. 273) provides that a person practising medicine without a license shall forfeit $100 for the first offense and $200 for each subsequent offense. Section 33 of article 6 of the State Constitution provides that all prosecutions shall be carried on "in the name and by the authority of the people of the State of Illinois," and concludes "against the peace and dignity of the same." In an action of debt for the penalty begun in a municipal court this provision of the constitution was not complied with in the statement of plaintiff's claim. Counsel for defendant contended that the suit was a prosecution, and that judgment for the plaintiff should be reversed for failure to obey the constitutional mandate. The Attorney-General contended that the question could not be raised on appeal because it was not raised in the trial court. It was held that the action was not a prosecution within the meaning of the constitutional requirement, and therefore need not conclude against the peace and dignity of the State; a "prosecution" being the institution and continuance of a criminal proceeding, as by indictment and information, in which sense the word is used in the Constitution.—People v. Gartenstein, Illinois Supreme Court, 94 N. E. 128.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

One Hundred Surgical Problems. By James G. Mumford, M.D. 354 pages; illustrated; cloth; price $3.00. W. M. Leonard, Boston, Publisher.

Manual of Surgery. By Francis T. Stewart, M.D. 682 pages; illustrated; cloth, price $4.00 net. Second Edition P. Blakiston's Son & Co., Publishers, Philadelphia.

Laboratory Studies in Tropical Medicine. By C. W. Daniels, M.B. Camb., M.R.C.P. Lond. 535 pages; illustrated; leather; price $4.00 net. Third Edition. P. Blakiston's Son & Co.

The Bellevue Hospital Nomenclature of Diseases and Conditions. By Robert J. Carlisle, M.D., Warren Coleman, M.D., Thomas A. Smith, M.D., and Edmund L. Dow, M.D. Revised and made to conform to the International Classification, 1911. 328 pages; leather.

Transactions of the Florida Medical Association for the Year 1911. Held at Tallahassee, Florida, May 10, 11, 12, 1911. 177 pages; paper; illustrated.

Klinik für Psychische und Nervöse Krankheiten. By Robert Sommer, M.D. 204 pages; paper; price 3 M. Carl Marhold, Halle a. S., Publisher.

Manual of Psychiatry. By J. Rogues de Fursac, M.D., and A. J. Rosanoff, M.D. Third Edition. Revised and Enlarged. 484 pages; cloth. John Wiley & Sons, Publishers, New York.

Howard Taylor Ricketts y sus Trabajos Sobre el Tabardillo. Mexico Tip. De La Vda. De F. Diaz De Leon, Sucs. Avenida del Cinco de Mayo y Motolinia. 133 pages; paper.

Hieronymus Fracastor's Syphilis, from the Original Latin. 57 pages; cloth; price $2.00. The Philmar Co., Publishers, St. Louis.

Lecciones Populares Sobre Tuberculosis. By Dr. J. A. Lopez Del Valle. Publicadas A Expensas de la Secretaria De Sanidad Y Beneficencia, Habana, Cuba. 62 pages; illustrated; paper.

Diät und Küche. By Dr. Wilhelm Sternberg. 188 pages; paper; price 5 M. Curt Kabitzsch, Würzburg, Publisher.

A Manual of Pathology and Morbid Anatomy. By T. Henry Green, M.D., F.R.C.P. Eleventh Edition. Revised and Enlarged by W. Cecil Bosanquet, M.A., M.D. 642 pages with 352 illustrations; cloth. Lea & Febiger, New York, Publishers.

Immune Sera. By Dr. Charles Frederick Bolduan. Fourth Edition. Rewritten and Enlarged. 226 pages; cloth; price $1.50 . John Wiley & Sons, New York, Publishers.

The Practical Medicine Series. Vol. V. Obstetrics. By Joseph B. De Lee, A.M., M.D., and Herbert M. Stowe, M.D. 223 pages; cloth; price $1.25. The Year Book Publishers, Chicago, Publishers.

Manual of the Diseases of the Eye. By Charles H. May, M.D. Seventh Edition, Revised. 407 pages; with 362 original illustrations, including 22 plates, with 62 colored figures; cloth; price $2.00 net. William Wood & Company, New York, Publishers.

A Manual of Clinical Diagnosis by Means of Laboratory Methods. By Charles E. Simon, B.A., M.D. Seventh Edition Enlarged and Thoroughly Revised. 778 pages; with 168 engravings and 25 plates; cloth. Lea & Febiger, New York, Publishers.

A Manual of Practical Hygiene. By Charles Harrington, M.D., and Mark Wyman Richardson, M.D. Fourth Edition, Revised and Enlarged. 850 pages; illustrated with 12 plates in colors and monochrome and 124 engravings; cloth. Lea & Febiger, New York, Publishers.

Pathological Technique. The New Fifth Edition. By F. D. Mallory, A.M., M.D., and James H. Wright, A.M., M.D., S.D. 507 pages; illustrated; cloth; price $3.00. W. B. Saunders Co., Philadelphia, Publishers.

The Modern Criminal Science Series.

Modern Theories of Criminality. B. C. Bernaldo de Quiros. Translated by Alphonso de Salvio, Ph.D. 249 pages; cloth. Little, Brown & Company, Boston, Publishers.

Criminal Psychology. By Hans Cross, J.U.D. Translated by Horace M. Kallen, Ph.D. 514 pages; cloth. Little, Brown & Company, Boston, Publishers.

CRIME; ITS CAUSES AND REMEDIES. By Cesare Lombroso, M.D. Translated by Henry P. Horton, M.A. 471 pages; cloth. Little, Brown & Company, Boston, Publishers.

VETERINARY BACTERIOLOGY. By Robert Earle Buchanan, Ph.D. 516 pages; with 214 illustrations; cloth; price $3.00. W. B. Saunders Company, Philadelphia, Publishers.

A TEXT BOOK OF MEDICINE. Vol. 1. By G. Dieulafoy. 1045 pages; illustrated; cloth. D. Appleton & Company, New York, Publishers.

A TEXT BOOK OF MEDICINE. Vol. 2. By G. Dieulafoy. 1036 pages; illustrated; cloth. D. Appleton & Company, New York, Publishers.

HANDBUCH DER SPEZIELLEN CHIRURGIE DES OHRES UND DER OBEREN LUFTWEGE. Vol. 1, 1st Half, No. 6. By Dr. L. Katz, Dr. H. Preysing and Dr. F. Blumenfeld. 208 pages; illustrated; paper; price 6 M. Curt Kabitzsch, Würzburg, Publisher.

HANDBUCH DER SPEZIELLEN CHIRURGIE DES OHRES UND DER OBEREN LUFTWEGE. Vol. 1, 2d Half, No. 1. By Dr. L. Katz, Dr. H. Preysing, and Dr F. Blumenfeld. 112 pages; illustrated; paper; price 6 M. Curt Kabitzsch, Würzburg, Publisher.

HYGIENE FOR NURSES. By Herbert W. G. MacLeod. 233 pages: illustrated; cloth; price $1.50 net. William Wood & Company, Publishers, New York

THEORY AND PRACTICE OF THYROID THERAPY. By Herbert Ewan Waller, M.R.C.S. England, L.R.C.P. London. 154 pages; cloth; price $2.00 net. William Wood & Company, Publishers, New York.

CARBONIC ACID SNOW AS A THERAPEUTIC AGENT IN THE TREATMENT OF DISEASES OF THE SKIN. By R. Cranston Low, M.B., F.R.C.P. 117 pages; illustrated; cloth; price $1.50 net. William Wood & Company, Publishers, New York.

LABORATORY MANUAL OF PHYSIOLOGY. By Frederick C. Busch, B.S., M.D. Second Edition. 212 pages; illustrated; cloth; price $1.50 net. William Wood & Company, Publishers, New York.

CLINICAL LECTURES ON THE ACUTE ABDOMEN. By William Henry Battle, F.R.C.S. 107 pages; illustrated; cloth; price $1.50 net. William Wood & Company, New York, Publishers.

AN INTERNATIONAL SYSTEM OF OPHTHALMIC PRACTICE. By Walter L. Pyle, A.M., M.D.

PATHOLOGY AND BACTERIOLOGY. By E. Trecaher Collins, F.R.C.S., and M. Stephen Mayou, F.R.C.S. 558 pages; illustrated; cloth; price $4.00 net. P. Blakiston's Son & Co., Philadelphia, Publishers.

A MANUAL OF MATERIA MEDICA. By E. Quinn Thornton, M.D. 525 pages; cloth. Lea & Febiger, New York and Philadelphia, Publishers.

HANDBUCH DER HYGIENE. By Prof. Dr. M. Rubner, Prof. Dr. M. v. Gruber, and Prof. Dr. M. Ficker. 410 pages; illustrated; paper; price 15 M. S. Hirzel, Leipzig, Publisher.

SÉMIOLOGIE RÉELLE DES SECTIONS TOTALES DES NERES MIXTES PERIPHERIQUES. By Prof. Henri Claude and Stephen Chauvet. 95 pages; cloth; illustrated. A. Maloine, Paris, Publisher.

TUBERCULOSIS HOSPITAL AND SANATORIUM CONSTRUCTION. By Thomas Spees Carrington, M.D. 164 pages, illustrated; cloth. The National Association for the Study and Prevention of Tuberculosis, Publishers.

CONTRIBUTION À L'ETUDE DE L'OPOTHÉRAPIE MAMMAIRE DANS LES HÉMORRAGIES ET DANS LE FIBROME DE L'UTERUS. By Dr. Jacques Luncz. 136 pages; Vigot Frères, Paris, Publishers.

DIE PALPABLEN GEBILDE DES NORMALEN MENSCHLICHEN KORPERS UND DEREN METHODISCHE PALPATION. By Dr. Tory Cohn. 585 pages; illustrated; paper. S. Karger, Publisher, Berlin.

HANDBUCH DER SPEZIELLEN CHIRURGIE DES OHRES UND DER OBERN LUFTWEGE. By Dr. L. Katz. 123 pages; illustrated; paper; price 9.00 M. Curt Kabitzsch, Publisher, Würzburg.

REPORTS FROM THE LABORATORY OF THE ROYAL COLLEGE OF PHYSICIANS, EDINBURGH. By Sir John Batty Tuke, M.D., and James Ritchie, M.D. Vol. X. Oliver & Boyd, Publishers, Edinburgh.

THOUGHTS OF A CATHOLIC ANATOMIST. By Thomas Dwight, M.D., LL.D. 243 pages; cloth; price $1.00 net. Longmans, Green & Co., New York, Publishers.

THE PRACTICAL MEDICINE SERIES. Vol. IV. GYNECOLOGY. By Emilius C. Dudley, A.M., M.D., and C. von Bachelle, M.S., M.D. 232 pages; illustrated; cloth; price $1.25. The Year Book Publishers, Chicago, Publishers.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ended September 30, 1911:

	Cases	Deaths
Tuberculosis Pulmonalis	464	167
Diphtheria	145	11
Measles	71	4
Scarlet Fever	75	5
Smallpox	—	—
Varicella	14	—
Typhoid Fever	122	17
Whooping Cough	49	8
Cerebrospinal Meningitis	6	4
Malarial Fever	—	
Totals	956	216

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended September 29, 1911:

THE PRACTICAL APPLICATION OF BACTERIAL VACCINES.*

By MARTIN J. SYNNOTT, A.M., M.D.,

MONTCLAIR, N. J.

It is a well-known fact that when an individual recovers from an infectious disease he is ordinarily in no danger of contracting it afresh, and that this non-liability continues for a longer or shorter period. There is no plausible explanation of this phenomenon other than that the infected system develops a resistance to the action of the invading pathogenic microbes which it did not originally possess, and that complete recovery is due to this resistance becoming strong enough to overcome and destroy these organisms. The problems involved in the development of such resisting powers have usually been studied under the term "Immunity," under which we include not only the non-susceptibility of an individual to a given disease and the power to resist infection, but also the mechanism by which a cure is effected.

According to the hypothesis of Sir Almroth E. Wright, when a patient recovers spontaneously from a bacterial infection, his cure is the result of immunizing responses evoked by the setting free of bacteria or their products from the focus of infection into the body, to which process Wright gives the name of "autoinoculation." Wright has demonstrated that it is possible to produce artificially in the human organism such immunizing responses by the hypodermic inoculation of bacterial vaccines which are derived from (autogenous) or correspond to (exogenous) the infecting microbes. This process he calls therapeutic immunization.

The essentials of success in the administration of vaccines are the knowledge and experience necessary so to determine the dosage and intervals between inoculations as to elicit the required immunizing responses and to bring the resulting antibacterial substances which circulate in the blood (opsonins) into the focus of infection.

In generalized infections bacterial products are almost constantly set free in the organism and we have a succession of autoinoculations. Immunizing responses follow in the cases which terminate favorably, because antibacterial elements are elaborated in the tissues and sent into the blood as a result of this stimulation. When a patient fails to recover this may be due either (1) to an inadequate or tardy immunizing response, or (2) to a severe or prolonged "negative phase" from excessive autoinoculations, which retard the body's immunizing responses, thus making possible the involvement of tissues previously uninvolved and the starting up of new foci of infection, or (3) to some interference with the free circulation of the blood containing the antibacterial agents through or about the focus of infection.

Vaccines aid in producing immunization only in subjects having the necessary power to react to this stimulus. If the immunizing mechanism of the body has been overwhelmed by excessive autoinoculations, as may easily be the case in general febrile infections and in septicemias where the infective bacteria are in the blood stream, further inoculations with vaccines may do serious and even fatal harm by inducing a permanent negative phase. The most we may hope for from vaccines in such conditions is to raise the patient's resistance by cautious *minimal* doses. In the strictly localized infections, on the other hand, where no autoinoculations are taking place, vaccine inoculations evoke prompt immunizing responses and the results from their proper use are preeminently satisfactory and brilliant.

In the generalized infections the use of vaccines should be left to the experienced immunizator. In this class determinations of the opsonic index as well as the careful and correct interpretation of the clinical symptoms are of great importance as a guide to their safe use. In the localized infections, however, no serious obstacles are ordinarily encountered and there is a clear field for vaccine therapy.

The dose should ordinarily be of such size as to produce a mild "negative phase" lasting not over 24 hours, followed in turn by a "positive phase" extending over two or more days. By the "negative phase" we mean a temporary reduction in the antibacterial power of the blood, characterized by malaise and slight increase in the local symptoms of the disease. During the "positive phase" there is an increase in the antibacterial power of the blood (opsonins) with clinical evidence of improvement in the patient's condition. He feels unmistakably better and very often will gleefully tell you so.

In generalized infections the dose should be reduced to the minimum because a negative phase of even a few hours' duration may lead to disastrous activity on the part of the infecting microorganism. A moderate negative phase in strictly localized infections can do no harm, because the opsonic content of the by-circulating blood does not immediately affect the disease focus. On the contrary the local reactive inflammation of this phase may do good by flushing the lesion with blood and an increased outflow of lymph, whereby a greater quantity of the blood's protective substances is carried into the infected area, and thus healing tends to result.

In our attempts at immunization we must not forget that if the focus of infection is sheltered from the blood stream by hyperplastic or scar

*Read before the Passaic City Section of the Passaic County Medical Society, in Passaic, N. J., October 12, 1911.

tissue, or is located in a joint where the opsonins in the blood do not have free access, we cannot expect the most favorable results. In such cases fomentations, poultices, massage, or Bier's apparatus may be resorted to with advantage in order to increase the local blood supply. Lymphogogues are indicated. Sinuses should be flushed with a hypertonic solution consisting of 4 per cent. sodium chloride and 1 per cent. sodium citrate in sterilized water. The use of this solution stimulates increased osmosis through the sinus walls, with a more copious flow of lymph, while the citrate in addition prevents coagulation. Infected cavities, such as the peritoneum or pleura, must be drained. Where we have sloughs, sequestra, or accumulations of pus, surgical removal is necessary, before any clinical effect can be expected from the immunizing responses following inoculations. On the other hand, where the microbes are fully exposed to the antibacterial substances in the blood a single inoculation may, under favorable circumstances, effect a complete cure.

The inoculations may be repeated every two to ten days, according to the size of the dose and the nature of the response elicited. The smaller doses are employed at the shorter intervals. The appropriate time for reinoculation is when the beneficial effects of the previous treatment are beginning to pass off. As recovery progresses the intervals between inoculations are gradually lengthened, and the size of the dose is increased. It is well to begin treatment with small doses. Ordinarily the inoculations are given twice a week.

Up to the present time, as might be expected, vaccines have been found most useful in diseases of bacterial origin causing local suppurative conditions where little or no general infection has occurred. In some of these diseases, notably pustular acne, the furunculosis group, sinuses, chronic cystitis or ureteritis—due to either the *B. coli communis*, gonococcus, staphylococcus, or tubercle—cellulitis, post-operative wound infections, subacute puerperal infections, chronic gonorrheal or tuberculous joint or other local lesions, chronic osteomyelitis, periostitis, otitis media, erysipelas, and many others, the results, when vaccines have been appropriately applied by *skilled hands*, have been almost uniformly brilliant and satisfactory; and the proof is now absolutely conclusive that many if not most of these disease processes are curable by bacterial inoculations.

In many of the diseases enumerated above clinical experience has been such that a fair degree of unanimity of opinion exists among immunizators and more or less definite rules as to dosage and frequency of inoculations have been laid down. It is in this class that estimations of the opsonic index may for the most part be dispensed with, and hence vaccines may be used more generally and by men whose inexperience would otherwise deter from availing themselves of the advantages of this valuable system of therapeutics.

Staphylococcal Infections.—Extensive staphylococcal infections producing carbuncles, boils, or abscesses, the so-called furunculosis group, were the first class of cases in which successful results were obtained with regularity and certainty at St. Mary's Hospital, London, by Wright and his associates, and treatment by vaccines in this group has been systematically applied. Cases of every degree of severity have been thus treated with almost uniformly complete cures.

Deep and widely extended carbuncles, no matter how stubborn, rapidly dry up and disappear soon after the treatment is commenced, showing that the system responds quickly and vigorously to the stimulus of the inoculation. Boils may be aborted after an early dose, or brought rapidly to a head, thus saving time and scarring. Furuncles seem almost to melt away after an inoculation, while in carbuncles the slough is rapidly thrown off. In fact in the whole furunculosis group of staphylococcal infections we obtain such good results and the efficacy of this treatment has been so repeatedly verified, that a cure may be promised in nearly every case.

The dose of a staphylococcus vaccine varies from 50 to 750 millions. In furunculosis a conservative initial dose might be 50 to 100 million cocci, and this dose may be repeated or doubled in four days; thereafter gradually increasing doses may be given every 4 to 10 days with the idea of producing permanent immunity and preventing a recurrence, until a maximum of 400 or 500 millions be reached. If, however, we wish to hasten the ripening of a furuncle or subcutaneous abscess or the resolution of a carbuncle the initial dose may be 250 to 500 millions, the idea being to produce a prolonged and marked negative phase by giving a maximum injection. The patient is benefited in this case because suppuration in the mass is thus hastened, with prompt breaking down and perhaps spontaneous evacuation of the pus. This is the one exception to the rule governing dosage and the negative phase. A smaller dose, say 100 millions, may be given at the end of a week, and thereafter inoculations may be repeated at first weekly, and later at longer intervals, increasing each dose by 50 or 100 millions until the maximum dose of 400 or 500 millions is reached.

Streptococci may be added if the patient does not get well, or if the trouble recurs. In such cases it is a safe guess that the difficulty is due to some other organism than the staphylococcus and if a culture is made from a pustule and examined streptococci are usually found.

Cystitis, ureteritis, sycosis barbæ, some forms of eczema, ciliary blepharitis, otitis media, sinuses left from abscesses and operations, felons, styes, suppurating acne, and septic wounds when caused by the staphylococcus have all yielded good results to inoculation treatment.

Streptococcal Infections.—Streptococcal infections constitute a large and very important group, in which excellent results have been obtained from inoculation treatment, particularly in the strictly localized forms such as abscesses, wound infections, local cellulitis, and lymphangitis, as a complicating infection in secondary tuberculous diseases, and in lupus vulgaris. Erysipelas will be referred to in detail in a later paragraph. The importance of this microorganism may be realized when we consider that infections due to its presence occur in most varied forms and are probably the true cause of many of the sequelæ and complications that follow grave infectious diseases, such as smallpox, scarlet fever, and diphtheria. These consequences may well be due, not to the direct action of the specific microbe that causes the disease but to its indirect action. The disease primarily enfeebles the system and lowers its resistance to pathogenic microbes like the streptococcus, which are practically ubiquitous but which, if present in the human body, are ordinarily kept under by the phagocytic power

of the blood. When this normal resisting power is greatly reduced by any disease, these microbes effect an entrance and attack important organs, such as the kidneys or the heart, thus causing the sequelæ which often do more injury to the patient than the original disease. To prevent these sequelæ the microbes that directly cause them must be fought against specificially, and therapeutic inoculation promises to furnish the mode of attack.

Pyorrhea alveolaris, otitis media, post-operative and subacute puerperal infections, chronic sinuses, pyemia, and osteomyelitis are among the many infections which may be due to this bacillus, and they all offer a promising field for vaccine therapy. In short the streptococcus in one or another of its strains is responsible for a very large proportion of our acute, chronic, and subacute infections.

Acute general infections such as septic endocarditis and puerperal septicemia must be left to the expert immunizator, who will determine the indications for or against vaccine inoculation and the dosage, by recourse to the opsonic index. In these infections very small doses only should be used, although it may be proper to repeat them frequently, in some cases daily, if they are used intelligently and in conjunction with the opsonic index. Improper inoculations in such diseases may hasten the patient's death.

In secondary streptococcal infections large doses are borne. A slight negative phase in such cases does no harm, because, as already pointed out, the local reaction of this phase flushes the lesion with blood and increased exudation of lymph, which help to effect a cure.

In many tuberculous conditions, a complicating streptococcal infection is often mistaken for an exacerbation of the original process.

The minimum effective dose of a streptococcus vaccine is 2 millions; medium doses range from 5 to 15 millions. Larger doses are dangerous and should not be used.

Parodontal Streptococcus Vaccine (Mixed).—Recently a stock "parodontal streptococcus mixed vaccine" has been prepared by Wright at St. Mary's, London, from cultures of streptococcus isolated from cases of pyorrhea alveolaris, dental abscess, and other infections of the teeth and gums. This vaccine has given good results in dental therapeutics. The dose is from 6 to 15 millions.

Erysipelas.—Vaccine treatment in this disease is a positive specific, and it may be administered safely without opsonic investigations. Dr. George W. Ross, of Toronto, who has had a very extensive experience in the treatment of erysipelas with streptococcus vaccine, recommends a vaccine prepared and administered with the following variations from the ordinary technique: (1) Sterilization of this vaccine is accomplished by the addition of enough carbolic to the original suspension to make it up to 1 in 200. Several days is usually enough to kill the cocci. Proof of sterilization is obtained by culture and the final vaccine is made so as to contain carbolic acid to the strength of 1 in 400. (2) The dose of this special vaccine is just one-half that of the ordinary stock vaccine, which is sterilized by heating to 60° C. for one hour.

The rules for dosage advised by Dr. Ross are as follows: Five million streptococci, devitalized by the above process, are given to a severe case in the first inoculation and ten million if the case is less severe. On the second day the severe case is given five million more if there be signs of improvement. The most important of these latter, according to Ross, is a clearing of the intellect, and less tenderness and pain in the local condition. There may be a moderate fall in the temperature on the morning following the injection. A drop of two or three degrees would be a valuable indication for a second inoculation. If the severe case shows no improvement the second inoculation should consist of only two and a half million. In less severe cases improvement is almost always manifest after twenty-four hours, and the patient receives half the first dose, or five million. Thereafter two and a half, five, or ten million are given every second day until a week after the temperature has reached normal, and the erythema has subsided. The severity of the infection must be our guide to dosage. "The more severe the case and the less satisfactory the clinical response the smaller the dose." The site of inoculation should be away from the area involved.

Acne.—Very brilliant results are obtained from vaccines in the treatment of acne. Even the most stubborn and deep-rooted cases yield so readily that a cure may be promised in nearly every case. A mixed vaccine containing twenty million acne or Sabouraud's bacillus and five hundred million staphylococci to each C. C. is ordinarily used at St. Mary's. Inoculations may be given every four to ten days, without recourse to the opsonic index, and even in the most desperate cases good results are very quickly apparent. A suitable initial dose for an average case is one hundred and twenty-five millions of staphylococci with five millions of acne bacilli, and this dose may later on be doubled. A negative phase from an overdose will aggravate the patient's condition and is to be avoided if possible. Treatment must be continued, at longer intervals, after the patient is to all appearances cured in order to prevent a recurrence. Relapses may be due to insufficient or too frequent doses.

In all non-pustular cases of acne, where comedones form the principal feature, the indications are to use a plain acne vaccine, but in all pustular cases, particularly where the lesions assume a subfuruncular form, the best results are obtained from the mixed vaccine of acne and staphylococcus.

Sabouraud's acne bacillus requires special technique to isolate and differentiate, and as the subject is so important and the results are so brilliant the following data obtained at St. Mary's are given somewhat in detail.

This bacillus has certain peculiar and characteristic individualities: (1) A temperature of 60° C. does not kill it. (2) It grows best on a fatty medium composed of ordinary agar with 1 per cent. oleic acid, neutralized with hydrochloric acid. The growth comes up slowly in five to seven days. It stains to the Gram stain. It dies quickly. (3) A culture may be secured in one of three ways; (a) from a pure laboratory culture; or (b) by giving our patient an overdose of acne vaccine, inducing a heavy negative phase, in this way producing a crop of pustules, and enabling us to thus obtain a culture from a pustule; or (c) bearing in mind that the usual contamination or mixed infection in acne is staphylococcus we may obtain a specimen of pus from a pustule, heat it for one hour at 60° C., which temperature kills everything except the acne bacillus. We then grow the culture, which will show only the acne bacillus.

It is important to daub the pus on the medium,

and not to smear it on, otherwise no culture will be secured. To obtain the pus specimen sterilize the skin with pure lysol, and then with alcohol. Pick or squeeze out the pustule, and set the pus specimen in a mass first at the bottom of the culture tube, then if enough remain, on four or five additional spots.

In this country the staphylococcus vaccine has been used somewhat in the treatment of acne, and while the results in pustular cases have been encouraging, treatment except with the mixed acne and staphylococcus vaccine or the acne bacillus vaccine is on the whole disappointing.

Local treatment and constitutional treatment should be given in conjunction with the inoculations. The writer has found the following local application of value:

Precipitated sulphur, dr. 4; powdered camphor, gr. 20; powdered tragacanth, gr. 30; lime water, oz. 2; rose water to make oz. 4. M. et Sig. Lotion. Rub in twice daily.

Even after a cure has been effected prophylactic inoculations should be insisted upon occasionally for several months, to prevent a recurrence, because relapses do sometimes occur.

Gonococcal Infections.—The best results obtained from vaccines in gonorrheal infections have been in arthritic cases and in chronic gonococcal urethritis. Chronic gonorrheal swellings, spondylitis, painful and persistent affections of the joints, yield readily to inoculations. Increased pain and stiffness in joint cases, or an increased discharge in urethritis, with general malaise, are the negative phase symptoms of an overdose. A stock vaccine must of course be used in joint cases, but these are not always of the same immunizing power, and the dose therefore will vary according to the virulence of the strain used in preparing the vaccine. This can be determined only by watching the opsonic index and the clinical symptoms of the negative phase.

Acute gonorrheal urethritis has been treated with vaccines, but care must be taken to avoid a severe or prolonged negative phase from an overdose, which would aggravate the symptoms. While for some unexplained reason the results have not been uniformly satisfactory in acute gonorrhea, successful cases are on record. An autogenous vaccine should be used, and early administration is important. Chronic or recurrent urethritis and gleet respond to autogenous vaccines, along with local treatment. In obstinate cases in this class we must be alive to the possibility of a straphyloccus or other complicating infection.

The minimum effective dose of a gonococcus vaccine is from one to two millions; medium doses are from five to twenty-five millions; the doses may be repeated every three to fourteen days—the smaller doses to be given at the shorter intervals. The stock gonococcus vaccine in use at St. Mary's is prepared from cultures of proved immunizing power, in two concentrations, viz., five millions and fifty millions of cocci per C. C.

Pneumococcal Infections.—The pneumococcus vaccine has been used by some immunizators with good results in croupous pneumonia, in protracted cases of pneumonia with delayed defervescence, in the less serious pneumococcic infections, such as "bronchial colds," and in cases of chronic bronchitis, providing of course that the pneumococcus is the predominant infection. The dose varies from ten to thirty millions.

In acute lobar pneumonia, because of the presence of autoinoculation, vaccine treatment should be left to the experienced immunizator, preferably one able to employ the opsonic index. Early administration is important, the initial dose being twenty millions. Where this dose brings down the temperature it may with advantage be repeated in two or three days, the curve of the opsonic index, or in default of this, the curve of the temperature, being here taken as a guide. A drop in the patient's temperature indicates improvement in the opsonic content of the blood. If the initial dose of twenty millions leaves the patient's condition unaltered, a further dose of thirty millions may be administered next day. Attempts at inoculation treatment in pneumonia by the amateur may prove disastrous and even fatal.

In the average case of pneumococcus catarrh, and in chronic pneumococcal bronchitis, an initial dose of fifteen to twenty millions is recommended. Where the pneumococcus causes infections outside of the lungs, as in otitis media, empyemata, sinuses, or cystitis, favorable results have followed inoculations.

Bacillus Coli Infections.—Bacillus coli infections of the urinary tract, producing nephritis, pyelitis, and cystitis, and infections in other parts, such as postoperative abscesses following appendectomy and herniotomy, are all suitable cases for inoculation treatment. Autogenous vaccines are necessary, as experience with stock vaccines of this microorganism has shown them to be very unsatisfactory.

Cases of acute bacillus coli pyelitis, cystitis, ureteritis and nephritis, with fever and other evidences of systemic infection, should, however, be left to the experienced immunizator, because they require opsonic estimations as a guide to safe dosage. Correct application of bacillus coli vaccine by skillful hands in cases of this kind have produced results varying from a complete cure to considerable amelioration of the symptoms of micturition, local discomfort, pyrexia, anaemia, and los of weight.

The dose of the bacillus coli vaccine is five to twenty millions every five to seven days.

Bacillus Typhosus Infections.—At St. Mary's a stock typhoid vaccine is prepared from a culture that has been frequently tested as to its immunizing power—in two concentrations—viz., one thousand millions and two thousand millions of bacilli per cubic centimetre. This vaccine is of undoubted value in treating local infections and suppurating foci caused by the bacillus typhosus, and as a prophylactic immunizing agent. The stock typhoid vaccine deteriorates with age, and should be used within three months from the date of its preparation.

In the vaccine treatment of typhoid fever experience has been too limited as yet to draw definite conclusions; therefore, the field should be restricted to expert immunizators. The investigations of Dr. W. H. Watters of Boston, Dr. J. G. Callison of New York, and others, encourage the belief that properly administered inoculations are of undoubted value in the treatemnt of this disease. Therapeutic doses seem to be without injurious effect, and a comparison of hospital cases so treated with a series of cases treated in the usual way indicates that in the inoculated cases the duration of the fever is shortened and relapses, sequelae and complications are less frequent. The mental effect upon the patient is very good, and compared with the non-inoculated cases the general appearance of the patients treated

with vaccines is happier and more comfortable. The more severe the case, the smaller should be the dose, and the inoculations are to be repeated at varying intervals, the small amounts being administered more frequently, sometimes at daily intervals. The dose varies from one to one thousand millions. Dr. Callison recommends an initial dose of three hundred millions as soon as the diagnosis is made, repeating the inoculation every third or fourth day, but increasing the amount at each inoculation one hundred millions, until one thousand millions are given. Dr. Watters prefers much smaller doses, his initial dose being not more than thirty to fifty millions. In one very critical case which, however, terminated favorably, the dose was only one million, but this was repeated daily.

Prophylactic Inoculation.—The inoculation of bacterial vaccines to produce immunity against various diseases opens up another very large field for investigation and experiment. The result of Wright's researches has positively demonstrated that in certain cases absolute protection may be obtained in this way. The most notable success has been with typhoid, against which disease it is possible to give substantial immunity to an individual without requiring him to undergo an actual attack of typhoid fever with all its attendant risks to himself and others. The introduction of dead typhoid microbes into the body has been found to be sufficient of itself to bring about immunizing responses which prevent the living microbe from making good its footing there. The wisdom of such a precautionary measure has been fully demonstrated and the protective value of typhoid vaccine has been as perfectly demonstrated as any fact in medicine, by most conclusive proofs. The importance of this discovery is very great both in averting threatening danger during an active epidemic, by inoculating the members of an infected locality who have escaped the attack, and in protecting travelers who are compelled to visit countries where typhoid fever is endemic. In this latter class are included the armies of occupation or conquest sent out to foreign lands.

Inoculations against typhoid have been successfully given for several years in the British army. The medical department of our own army has also recognized the great importance of this discovery, and experiments were begun in March, 1909, to test the effectiveness of prophylactic typhoid immunization. Since that date there have been over 45,000 inoculations of which complete record cards have been kept. Not a single bad result has been reported after the administration of the vaccine. Over 95 per cent. of the men had little or no reaction or discomfort aside from a somewhat tender spot on the arm, which was rarely troublesome, and disappeared in twenty-four to forty-eight hours, and in the last series of 27,000 the reaction remained absent or mild in 99 per cent. In the 45,000, only eleven cases of typhoid with no deaths have been reported, and in at least four of these the diagnosis was not confirmed and there remains some doubt as to its correctness. The procedure has now been regularly adopted in the U. S. Army as a routine measure, and all recruits upon being sworn in are vaccinated against both smallpox and typhoid fever.

Major F. F. Russell, M. D., U. S. A., to whom the writer is indebted for the foregoing data, further informs me that for a long time frequent estimates of the agglutins, opsonins, and bacteriolysins, and in a few cases of the complement fixation-power of the serum of the immunized patient were made. The results were uniform in showing the production of a high degree of immunity, but at the present time only occasional determinations are made.

In the U. S. Navy the writer is informed by Dr. W. C. Braisted, acting chief of the Bureau of Medicine and Surgery, that prophylactic inoculations against typhoid fever have been administered to about 3500 of the personnel of the Navy. No serious results have followed these inoculations, which appear to have effectively prevented the spread of typhoid fever among the 2200 marines encamped at Guantanamo, Cuba, and also to have controlled an epidemic at the Training Station, Norfolk, Va. At the present time the exact figures are not available, but as far as known there has been no case of death from typhoid fever among those having had three doses of the vaccine.

The immunity against typhoid fever obtained by prophylactic inoculations has been shown to last several years. In this connection it is important to remember that the Widal reaction as a means of diagnosis among persons who have been vaccinated is worthless, since the reaction appears immediately after immunization and persists for a variable length of time. In some cases now under obervation it is still present after a year and a half. Among such patients the only rational way of confirming a clinical diagnosis by laboratory methods is by resorting to blood cutures.

The dosage has been definitely determined. In England one thousand million devitalized typhoid bacilli are administered to an ordinary healthy adult and the patient is advised to rest in bed until the next afternoon. A slight and varying amount of malaise, headache, and possibly joint pains, will occur, but they usually pass off in twenty-four hours. Not less than ten days subsequent to the initial injection a dose of two thousand millions is given, and a similar sequence of symptoms may follow, but is usually less marked than after the primary inoculation. Only two inoculations are deemed necessary to give complete immunity, and estimation of the opsonic index in connection with prophylactic immunization against typhoid is not determined. In the U. S. Army the dosage is five hundred millions for the first and one thousand millions for the second and third doses, and the patient is advised not to use alcoholic drinks or to take active exercise. He is encouraged to attend to his ordinary business, and as a rule is able to do so. Three doses are administered. The patient is never advised to remain in bed after the inoculation, this being considered unnecessary.

In prophylactic inoculation against the gonococcus doses up to two hundred millions have been given to normal men without marked symptoms. A safe commencing immunizing dose to a healthy individual would be about one hundred millions. This inoculation should be repeated in a week with a larger dose, about two hundred millions, if the first dose did not produce any marked symptoms. The immunity produced in this way should last for several weeks. Prophylactic immunization against gonorrhea is important where marriage is contemplated between individuals one of whom has had the disease, for the protection of the uninfected party to the contract. This applies equally to cases where the disease is contracted innocently or otherwise by a married man or woman, and we wish to prevent the infection of the healthy partner.

With regard to prophylactic inoculation against influenza very little has been done. Captain S. R.

Douglas, Sir A. E. Wright's associate at St. Mary's Hospital, London, informs the writer that he once gave himself a dose of fifty millions of the influenza bacillus vaccine when it was first made without any more discomfort than a slight local reaction. He suggests giving repeated doses, and increasing them as long as they do not produce any marked clinical symptoms. How much immunity is produced or how long it lasts is not known, but Captain Douglas believes one might measure the agglutinins after the second inoculation.

The evidence in favor of prophylactic inoculations is accumulating in a growing mass, so that we may hopefully look forward to the time in the near future when if danger threatens us we can by these means so stimulate the latent capabilities of the immunizing mechanism of the body that when disease attacks the bodily defenses will be prepared to repel the assault.

Tuberculous Infections.—The methods of therapeutic inoculation have been used most largely and with the greatest prospect of doing good by Wright and others in tuberculosis, more particularly the chronic, strictly localized and apyrexial infections, *i.e.,* tuberculous glands, cystitis, ulcers, sinuses and deposits in the joints and bones.

The number of patients suffering from such troubles is very great, and the number of invalids and cripples caused by tuberculosis is increasing every year. Tuberculous infections may be found in any part of the human system, and when we consider this fact and realize how large a proportion of the human race suffer from this infection the value and importance of a specific treatment that can reach it wherever it may be located becomes very evident.

It has been found that under proper inoculation treatment in the class of cases enumerated above, the symptoms gradually improve, the deposits shrink and disappear, and in the majority of instances a successful outcome may be safely predicted as a normal consequence of the treatment, although of course success cannot be expected in every case, or until after a prolonged course of treatment. The results at St. Mary's have been most brilliant, and leave no reasonable doubt that the recoveries have been due directly to the effect of the inoculations.

Tuberculous glands under tuberculin inoculation treatment are a triumph for this system of therapeutics. Such cases rarely fail. When inoculations are given as post-operative treatment in tuberculous lymphnoditis we find that less radical surgery is required, recurrence is prevented, and it is not so essential to excise all the infected tissue. Where the inoculations have been resorted to prior to operative treatment, liquefaction and pus formation result more quickly, and removal may be accomplished through a small puncture or a large aspirating needle, care being observed to avoid secondary infection. Continued inoculation treatment results in a cure, without recourse to packing or drainage tubes, and the resulting scar is very slight.

Tuberculous iritis, cystitis, dermatitis, nephritis, epididymitis, orchitis, peritonitis, and bone or joint lesions, have all yielded to inoculation treatment in the hands of experienced immunizators. Immediate results should not be looked for from inoculation treatment in suitable tuberculous infections as six to nine months is usually the shortest period required for a cure. The prognosis is better if treatment is begun early.

We must bear in mind in treating bladder cases that even after a cure has been effected the frequent micturition often continues, because scar tissue has formed, and when this is put on the stretch by the presence of urine in the bladder, there is a desire to urinate. This applies equally to all severe cases of cystitis after a cure has resulted, whatever the infecting microorganism may have been. It is well to forewarn the patient of the possibility that this symptom may continue even after the disease has been cured.

Pulmonary phthisis is a theme by itself. Inoculations with tubercle vaccine should not be resorted to while active symptoms are present, but the cough and fever should first be allayed and the patient kept quiet and at rest. Such cases should be treated only by an expert immunizator and opsonist, otherwise, as previously pointed out, serious if not fatal harm may be done to the patient. Here the opsonic index is most important.

In treating phthisis, where the sputum shows a great many pneumococci with a few tubercle bacilli the indication would be, of course, to try a pneumococcus vaccine, made from an autogenous organism, and at the same time endeavor to raise the resistance to the tubercle as well, warning the patient that such an attempt will naturally take time, and that six months will be the shortest period in which we may hope to accomplish anything. This applies equally to any other complicating infection such as the streptococcus.

In inoculating for phthisis the dose should be very small because there is a certain amount of spontaneous antoinoculation taking place from the diseased areas in the lungs, hence a dose suitable one day might be excessive the next, a fact which emphasizes the importance of the opsonic index as a guide to the dosage in such cases. A negative phase of only a few hours' duration might give rise to disastrous activity on the part of the tubercle bacillus.

Bacterial vaccines are standardized in such a manner as to contain in each c.c. a specified number of microbes, except in the case of tubercle vaccine where each c.c. contains a specified weight of the powder obtained by the comminution of tubercle cultures. The tubercle vaccine thus prepared at St. Mary's from tubercle bacillary emulsion (B. E.) is put up in three strengths, viz., 1/2000th, 1/5000th and 1/25,000th milligramme of dried comminuted tubercle bacilli per cubic centimeter. By simple calculations doses from the minimum to the maximum may readily be determined. The dose varies from 1/100,000th to 1/3000th milligramme, at four to ten-day intervals. The increase should be cautious and gradual, with the exercise of extreme care to avoid any clinical symptoms of a negative phase. In generalized tuberculosis, such as phthisis and tuberculous peritonitis, larger doses than 1/50,000th of a milligramme are to be given with the greatest caution, and in advanced cases such a dose even may be excessive. In strictly localized infections in adults the doses may range from 1/15,000th to 1/10,000th of a milligramme. The larger doses are to be given only to the mildest afebrile cases, where the infection is slight, and there is no lung involvement.

The dosage may be summarized thus: The minimum effective doses vary from 1/100,000th to 1/50,000th milligramme, in extensive infections; and from 1/15,000th to 1/10,000th in slight infections; maximum doses vary from 1/6000th to 1/3000th milligramme, these latter to be used only

in afebrile, mild and localized infections. The doses would be much smaller for children.

It is always very important to determine whether or not there is any lung involvement, before beginning our inoculations for any localized trouble such as a tuberculous lymphatic gland, in which case the size of the dose should be reduced to 1/50,000th or less. If the lung involvement is considerable, inoculations should not be resorted to, except in conjunction with estimations of the opsonic index.

Influenza Infections.—A vaccine may be prepared from cultures of the Pfeiffer influenza bacillus isolated from cases of acute influenza or chronic bronchitis caused by this bacillus. This vaccine is applicable to every case of "grip" or complicating infection where the influenza bacillus has been identified. The dose varies from five to fifteen millions. A stock vaccine is prepared at St. Mary's Hospital, London.

The Neoformans Vaccine.—The *"Micrococcus neoformans"* of Doyen, which is a microbe of the staphylococcus family, is found in most malignant tumors, and in almost every carcinoma. Wright's theory concerning this microorganism is that it is a secondary infective agent which invades the tumor and that it is not the primary causal agent of the cancer; it is responsible for the suppurative and inflammatory changes and much of the pain commonly associated with malignant growths, besides having much to do with the development of the cachexia. The neoformans vaccine has been demonstrated to be a valuable therapeutic agent in relieving pain, controlling local inflammation, and indirectly prolongs life by diminishing the cachexia. It is a valuable aid to differential diagnosis between cancer and syphilis in connection with the opsonic index. The initial dose is fifteen millions, cautiously increased to thirty millions. An overdose may greatly aggravate the pain. The site of the inoculation should be away from the tumor.

Diseases of the Accessory Nasal Sinuses.—In infections of this class, such as empyema of the frontal sinus, autogenous vaccines may be readily prepared. The initial dose should be much smaller than ordinary on account of the limited space for the reactive inflammation accompanying a severe negative phase, should the dose be large. The dosage should be increased as rapidly as possible. The length of interval between inoculations will depend on the amount of reaction following the injection, but as a rule one should give the smaller doses two or three times a week and finally get to a point where a single large dose will keep the immunity up for several days.

Concluding Remarks.—Bacterial vaccines probably retain their efficacy for an indefinite period. The one notable exception to this dictum is the typhoid vaccine, which should be used within three months from the date of its preparation, as experience seems to indicate that it becomes inert after this period. All vaccines should be kept in a cool, dark place.

When it is possible to have an autogenous vaccine prepared by a competent bacteriologist, this procedure is ordinarily to be preferred to inoculations with a stock vaccine. It is always proper, however, to use a reliable stock vaccine while we are waiting for an autogenous one to be prepared. Two of our large manufacturing biological companies early sent physicians to St. Mary's to learn Wright's technique and these men are now in charge of the manufacture of vaccines for their respective concerns.

The stock staphylococcus vaccine is used at St. Mary's for practically all staphylococcal lesions, and only very rarely has it been necessary to make a special autogenous vaccine. The stock streptococcus vaccine is used initially in acute cases, but as soon as the infecting streptococcus is isolated an autogenous vaccine is prepared, this having been found to be much more specific. The stock streptococcus vaccine gives very satisfactory results in the treatment of erysipelas.

In colon bacillus infections an autogenous vaccine is always prepared, because a stock vaccine has been found to be of very little use. In gonorrheal infections, outside of the urethra, stock vaccines must be relied upon, because of the difficulties in the preparation of autogenous ones. The stock acne vaccine, the stock influenza, neoformans, tubercle and typhoid vaccines have all proven very satisfactory. If a stock vaccine is giving satisfactory results it is always proper to continue its use, otherwise a special vaccine should be prepared and used before abandoning the treatment, particularly if the case is one where a vaccine is clearly indicated. If no benefit results from our vaccine inoculations in a suitable case, the possibility of the existence of a mixed infection must not be overlooked.

The opsonic index, when estimated by a careful and well-trained laboratory worker, although perhaps not mathematically exact, is a valuable guide to dosage and the proper interval between inoculations. The opsonic technique, however, is difficult to acquire. Special and expensive laboratory apparatus is necessary, and considerable experience and skill are essential if reliable results are sought. It also consumes time, each estimation requiring at least one half hour. Many successful immunizators are learning to dispense with it except as an occasional confirmatory control. Some vaccine therapists have become so expert that they have discarded blood examinations altogether and rely entirely upon the careful study of the clinical signs as a more valuable indicator for dosage.

Prominent among the inoculators who are discarding the opsonic index as a guide to dosage is Dr. W. D'Este Emery, a very well-known English immunizator and author. His plan is to watch the clinical symptoms carefully and to use gradually increasing doses until large amounts are given. He believes his results have been better since he adopted this procedure than when he depended upon the opsonic index as a guide. In a recent letter to the author of this paper he writes: "I think we have now reached a stage in vaccine therapy similar to that to which we have passed in the use of tuberculin. No one who has used both the opsonic method and the method of gradually increasing the dose until large amounts are given, is likely to stick to the former."

On the other hand the enthusiastic opsonist will tell us that where estimations of the opsonic index are determined the progress of the patient is more satisfactory, because the inoculations may be safely increased, if the indications are to do so, whereas without the index to guide us, conservative therapeutics might suggest such small doses that the progress of the disease would not be arrested, and the cure of the patient needlessly delayed. By means of the index also, we are able to determine what nature is doing in the way of autoinoculations, and with it as a guide, the expert opsonist

may safely inoculate in certain acute febrile infections, where otherwise the use of bacterial vaccines might be contraindicated.

In the matter of dosage, it is the experience of most conservative immunizators nowadays that smaller doses are to be preferred, at least in beginning treatment, to the very large doses reported, sometimes disastrously, in connection with the earlier experiments with inoculation therapy. Generally speaking, the more severe the infection, and the more pronounced the clinical symptoms, the smaller should be the dose of vaccine employed. Ordinarily the inoculations are repeated twice a week, but where very small doses are used, they may be given more often, in some cases daily minute doses being advantageously employed. *Vice versa,* when the size of each dose is increased to a large amount, the intervals between inoculations should be lengthened.

Finally, we must not regard vaccines as a "panacea" or cure all. Considerable patient study and preparation are necessary to understand their limitations and contraindications, and special knowledge and skill is required if one is to employ them successfully or at all times safely. Their improper application, particularly in acute general febrile infections, may do serious harm, and on account of this danger they should be used only by the duly and properly qualified.

MOVABLE CECUM AND TYPHLOTOMY.

BY OTTO LERCH, A.M., M.D., PH.D.,

NEW ORLEANS.

PROFESSOR OF MEDICAL DIAGNOSIS, NEW ORLEANS POLYCLINIC.

PAIN in the region of the appendix is not rarely found and, as it is one of the most important diagnostic signs of appendicitis, is regarded with apprehension by patient and physician. Appendicitis is always a very serious disease and has to be watched with the greatest care. Though the beginning of the trouble may be light and promise speedy recovery, complications may arise at any moment necessitating an immediate operation. Pain over McBurney's point, tumor, fever, constipation, rigidity of the recti, high pulse frequency, leucocytosis, and a characteristic tongue are symptoms that exclude any other affection. The disease and its complications is so much dreaded that up to the present it has been considered correct practice to remove the appendix when slight symptoms point to that region and many an appendix has been removed in which even the operating surgeon was not able to discover a lesion of any consequence. Frequently the troubles persist after the appendectomy. This view is gradually inducing a change towards a more conservative practice. In Fischel's article on this subject, published in the June number of the *Müenchner medizinische Wochenschrift*, he quotes Hausmann and others who have studied and described a condition characterized by (1) pain in the cecal region, spontaneous and colicky, or felt only on palpation and intermittent; (2) gurgling in the ileocecal region and a tumor felt like an air cushion, very painful, on deep palpation; (3) intestinal disturbances; either severe constipation or alternating diarrhea and constipation.

The author calls attention to the absence of the other symptoms of appendicitis—rigidity of recti, leucocytosis, the characteristic tongue, and fever, though he admits having seen cases of cecum mobile with light fever. Skiagraphic views have shown widening and excessive mobility of the cecum, retention, and slow motion of the chyme in the cecum and ascending colon in this condition.

These investigations prove beyond all doubt the local character of the trouble, and the views regarding the clinical picture of the disease are unanimous, though the explanation as to their etiology differs. A typhlitis stercoralis and constipation with torsion of the cecum are considered to cause its mobility and descent with accompanying pains and tumor.

Klose adds that anomalies of development may be at the base of this condition, though a movable cecum does not necessarily cause pain. Some claim to have cured the trouble by fixation of the cecum, others by cutting adhesions and mobilizing it still more.

Fischel denies the mobility of the cecum and constipation to be the cause of the trouble, because in some a mobility of the cecum is not found and because in others the trouble has been cured by increasing its mobility. He denies the constipation to be the etiological factor, because many of these patients suffer from diarrhea. This observer claims chronic catarrhal typhlitis to be the cause of the trouble, producing motor insufficiency and atony with consequent slow movements, retention of chyme, fermentation, pain, constipation, diarrhea, and gaseous tumor, favored occasionally by a movable cecum. He insists that this condition offering a well-characterized clinical picture ought to be named "typhlatonia," and not "*Cæcum mobile,*" and warns against too frequent surgical interference. The report of cures obtained by diametrically opposite procedures, fixation and mobilization of the cecum, leave doubt as to their efficiency, especially as the rest and dietetic treatment following every laparotomy must favorably influence the disease, and as remission of many years' duration is known in its course. The changing condition of the catarrh explains the changing severity of pain and the remissions, though torsion and pulling of the distended cecum and the mesenteries may explain some of the painful attacks.

I have met with this condition characterized by pain in the region of the cecum, by a tumor gurgling and painful on palpation, and by intestinal disturbances—constipation or diarrhea or both, changing from one to the other. I have observed patients, not fully and quickly relieved by medical treat-

ment, insisting upon an operation, where the appendix was found practically in a normal condition, the pain persisting after the appendectomy, which in each case was performed.

I have studied this condition for a number of years in patients suffering from an enteroptosis, have a number of cases in my records, and used to call it pseudoappendicitis. I never have found it without enteroptosis as the underlying condition, and always have been under the impression that it was a symptom complex of this underlying trouble. This is easily recognized when well developed, but difficult to diagnose in fat patients in whom palpation of a movable kidney is often impossible, and the descent of the stomach is difficult to demonstrate.

In a paper on "Percussion, and Percussion of the Kidney" (MEDICAL RECORD, February 4, 1911), I have shown how at least some of the difficulty may be overcome. The drop kidney and its mobility may be readily demonstrated by percussion, no matter how fat the patient. I have called attention to the fact that one examination is in many instances not sufficient, as the kidneys will slip in place and resume the normal position when the patient lies horizontally, face downward, and it is frequently necessary to have this patient roll himself over to displace the kidney again.

In an article on "Displacement of the Abdominal Organs" (MEDICAL RECORD, December 9, 1905), I state that pains simulating appendicitis are a frequent symptom and, as to be expected, the intestinal functions are always disturbed, flatulency and constipation being common, though diarrhea may be found alternating with constipation. Large flakes of mucus are often passed, though their passage does not cause pain in every instance. One patient of mine passed for weeks at a time masses of jelly-like mucus without the slightest pain, and there was no pain on pressure along the colon, though the appearance of the mucus in the stools greatly affected and worried her. A dislocation of the intestines, which always may be found in these cases, coupled with the disturbance of the nervous system causing hypersecretion of mucus, explains these peculiar symptoms.

As stated, I have for many years recognized this condition—pain in the appendix region, gurgling tumor and intestinal disturbances, constipation and diarrhea, occurring as a symptom complex accompanying enteroptosis. Instead of the gaseous tumor in the ileocecal region, I have frequently found a contracted colon, feeling like a smooth, hard cylindrical tumor, sometimes alone, sometimes coupled with a contracted transverse colon or flexure, rarely more than one or two sections of the colon being contracted at the same time. This condition accompanied by the same symptoms—pain, paroxysmal and colicky—or on palpation in the appendix region, with intervals free of all pain, and constipation or diarrhea or both alternating.

Not denying that this well-characterized clinical picture as described by Fischel and others may occur without enteroptosis, I wish again to call the attention to the difficulty of diagnosing it in fat people. We find two main types of enteroptotics: one with an *abnormally straight spine, the other with the lumbar curve greatly exaggerated.* Those of the former type are usually very thin and emaciated, those of the latter type well nourished or obese, and it is in this type that the affection is difficult to recognize. However the nervous and gastrointestinal symptoms, the history, the chronicity and progress of the trouble, etc., call at once attention to the affection and we may find on a second examination proof overlooked on the first. As mentioned before, the kidney can be readily percussed, but will often slip in place when the patient is in position for percussion. Absence of kidney dullness, kidney dullness displaced downward or changing but slightly on change of position, with absence of symptoms of nephritis make the diagnosis. I agree with Fischel that the catarrh is in most cases, if not in all, the direct cause of the trouble. The constipation which is most frequently present calls for purgatives to empty the bowels and the constant use of these is alone sufficient to cause catarrh; once this is well established, diarrhea will alternate with constipation and if the condition is not relieved will finally end in continuous diarrhea. A frequent spastic contraction of the colon preventing the contents of the colon from moving normally, may also be the cause of Fischel's typhlatony.

Fever is occasionally found, sometimes prolonged and serious due to autointoxication, and a busy practitioner, even if not taking it for appendicitis, will occasionally mistake it for ptomaine poisoning.

Though I have found this syndrome only with enteroptosis, it is a well-characterized clinical picture simulating appendicitis and to be differentiated only by the absence of other prominent symptoms of this disease. Neither does it matter whether we name it movable cecum, with Hausmann and others, or call it with Fischel, typhlatony, so long as it will lead to a more conservative surgery and save people from having the belly cut open for an appendicitis that does not exist, and the appendix removed because found too long, too short, or bound down by adhesions. However, if there is any doubt as to the diagnosis we have to remember that appendicitis is a serious disease, and it is wise to watch the course with a surgeon.

I report a few cases to illustrate the subject:

CASE I.—Mrs. W. R., thirty-five years of age, no children, wife of a physician. Her family history is negative, except that she states her mother to be of a very nervous temperament. She passed through diphtheria, scarlet fever, and the other diseases of childhood and later had several attacks of malaria and ptomaine poison. Came to me three years ago complaining of gastrointestinal troubles, diarrhea and constipation alternating, severe paroxysmal pains in the region of the appendix, and a history of constipation for many years previous to the attacks of pain in the appendix region and diarrhea. The patient is very nervous, complains of nervous chills and various other hysterical and neurasthenic symptoms. Height, 5 ft. 5½ inches; weight, 93 pounds. Organs normal. The lower curvature of the stomach is a hand's width below the navel; the right kidney is palpable, both kidneys are displaced downward (percussion); the uterus is prolapsed and a gaseous tumor is felt in the cecal region, very painful and gurgling on palpation. The patient had an exceptionally light attack last winter lasting only a few days, following mental strain and indiscretion in diet, whereas previous attacks diagnosed as ptomaine poisoning had lasted weeks at a time. With this exception she has been free of all troubles during the last two years. Her present weight is 118 pounds.

CASE II.—Mrs. H. F. P., forty-four years of age, wife of a farmer; three children, one living,

two dead, soon after childbirth. People on mother's side very nervous, otherwise her hereditary history is negative. Passed through diseases of childhood and various attacks of malaria and grippe. The patient is very nervous, compains of sour stomach, severe constipation since last child was born, seventeen years ago; cutting and tearing pains in the region of the appendix from time to time, though for weeks and months she may be free of these pains. With this she presents a number of nervous symptoms; chills which she calls nervous, trembling, exaggerated knee reflex, absence of uvula and cornea reflex, pressure points of pain, choking sensations, etc. Height, 5 feet 5 inches; weight, 95 pounds, when first seen on June 29. Organs found normal. Stomach stands out like a bladder below the navel. Both kidneys are prolapsed and palpable. Uterus prolapsed, flexure contracted, gaseous gurgling tumor felt in cecal region, painful on pressure. The patient rapidly improved under treatment.

Case III.—Miss A., twenty-two years of age; family history negative. Passed through diseases of childhood and was once treated for appendicitis. Seen first March, 1908. Complains of severe pain in the region of the appendix and constipation for many years. Depends on daily dose of purgatives to empty bowels. Organs normal. The right kidney is palpable; the lower curvature of the stomach is below the navel; the appendix feels like a pencil. Improved under treatment. I then lost sight of her for some time and heard that two years later laparotomy was performed, appendix was found practically normal but was removed. Since then she has had several attacks of pain in the appendix region and has just returned for treatment.

Case IV.—H. B., twenty-four years of age, clerk. Hereditary history negative. Former diseases, measles and scarlet fever. Patient nervous, constantly worrying about himself. First seen in January, 1908. Complained of constipation for years and severe paroxysmal pains, starting around the navel and settling in the appendix region. Organs normal. Right kidney displaced downward, lower curvature of stomach at navel, transverse colon contracted. Patient improved and was free of all troubles for several years. A new attack occurred after an indiscretion in diet and laparotomy was advised by the attending physician, and appendix found bound down by adhesions.

These histories are but few of many of patients presenting pain in appendix region, gastrointestinal disturbances, constipation, and constipation alternating with diarrhea, a gaseous painful gurgling tumor in cecal region, and spastic contraction of some section of the colon. The laporotomies performed did not disclose appendicitis and relief after appendectomy was not obtained. I treat these patients with rest, if necessary in bed for some time, if there is fever, otherwise intermittent rest, specially after the main meal at noon, and early bedtime to relieve the circulation. I find that many of these patients sleep on their stomach, a position allowing the kidney to float in position and that they sleep without a pillow. I therefore advise them to place bricks under the foot of the bed to facilitate the replacement of the abdominal organs, empty them, and increase the flow of blood to head and chest. This with the intermittent rest saves heart and vessels, the face and chest fill out even before the gain in weight is at all considerable. These patients with pendulous flabby abdomen look pale and anemic, although the blood is found in perfect condition; this is due to its distribution, too much in the abdomen, not enough in the other organs and the periphery, which expains also the cold and clammy hands, the nervous chills, the contracted arteries, and the nervous symptoms. A careful selection of diet, indicated by climate, season, state of nutrition of the patient and condition of stomach and intestines. Hot moist applications or Prissnitz bandages, later the cold sitzbath and douches, with some general tonic, and hydrotherapeutic measures at night if sleeplessness is complained of. Atropine or belladonna combined with sodiums, sulphocarbolate or some other intestinal antiseptic to counteract pain, fever, and excessive diarrhea, and other drugs that may be indicated to influence the gastric and nervous symptoms, the anacidity or excessive acidity of the stomach contents, etc. Intestinal antiseptics are made light of and discarded by many; it seems to be the idea that they are useless because they are insufficient to sterilize the intestines. Sterilization of the intestines cannot of course be reached, neither can it be the aim of the treatment. Just as in fever which has long been recognized to be beneficial when it runs a certain course and presents a certain temperature curve, we give antipyretics only to reduce hyperpyrexia, so in intestinal diseases it can only be the object of treatment to reduce an excessive fermentation and that can be readily done with our therapeutic means and will be always found of benefit and will influence the course of the disease favorably. Massage lightly given along the course of the colon and later when the acute condition has passed more thoroughly and given with the object of relieving constipation and strengthen muscles, combined with suitable exercises, is always of value in the treatment of this disease.

A well-supporting bandage is indicated in almost every case. Most of the bandages on the market are cumbersome and do not support, they fit to the abdomen like a glove and not at all in thin persons. I have designed a bandage that meets the indications and have described it in a previous publication. It consists of a piece of elastic, which is fitted above the pubes in front and held by legstraps and three elastic straps buckled to a second shield across the spine. These straps secure a backward and upward pressure and are easily regulated by the patient so as to be comfortable. The bandage is not cumbersome and gives full support. With a treatment carried on along these lines and with the final object of strengthening the abdominal muscles and promoting better blood distribution, the patients usually do well.

1628 Upperline Street.

QUININE AND UREA HYDROCHLORIDE: ITS PREPARATION, AND ITS USE AS A LOCAL ANESTHETIC, WITH A REPORT OF TEN CASES.

By WILLIAM A. BOYD, B.S., M.D.,

WESTPORT, CONN.

No argument in favor of the use of this form of local anesthesia has ever been more forcibly presented than when Dr. L. J. Hirschman said, "the use of any agent which will prevent operative pain while not interfering with the consciousness of the patient or endangering life by interference with respiration, circulation, or elimination, is cer-

tainly a great step in advance in surgery." It is the purpose of this paper to review some of the literature which has been published on the subject of the use of quinine and urea hydrochloride as a local anesthetic, referring to its preparation and its introduction, reporting several of my own cases as a supplement. At the conclusion is given a list of the articles published on the subject which I have been able to find in periodical literature.

This preparation is also known as chininum bihydrochloricum carbamidum, urea quinine, and quininæ carbamidum. It is a double salt of quinine and urea, and is prepared by dissolving 400 parts of quinine hydrochloride in 300 parts of hydrochloric acid, adding to the solution 60 to 61 parts of pure urea, warming the mixture until dissolved, filtering it through glass wool and allowing it to crystallize. Urea hydrochlorate and urea hydrochloride are synonymous.

Properties.—It is soluble in its own weight of water or in alcohol. It is also soluble in 800 parts of chloroform. It occurs in colorless crystals, which form as four-sided prisms, or as a white powder. Aqueous solutions are acid. It is non-irritating when injected hypodermically, and produces local anesthesia. It contains 70 per cent. of alkaloidal quinine and about 17 per cent. of urea hydrochloride.

For the production of local anesthesia injections of a solution of from ¼ to 1 per cent. strength are used. The ¼ per cent. solution is said to be free from the risk of producing fibrous indurations, which sometimes occurs with the stronger solution. For minor operations I believe the 1 per cent. solution is the strength of choice. A 1 per cent. solution may be made by dissolving 5 grains in 1 ounce of sterilized water. This is not exactly 1 per cent., but near enough for ordinary purposes. It is also prepared in ½-grain hypodermic tablets. One tablet dissolved in 50 minims of sterilized water yields a 1 per cent. solution.

Method.—The solution is administered in precisely the same way as cocaine. The amount used in an operation varies from 2 to 15 c.c. The fluid should be injected slowly and under light pressure into the area to be anesthetized.

To Dr. Henry Thibault of Scotts, Ark., must be given the credit of first calling the attention of the medical profession to the use of this anesthetic. On September 15, 1907, he read a paper on this subject before the Medical Society of Arkansas. In this he stated that the anesthetic properties of quinine had long been recognized, and that it had power to inhibit nervous action by contact with terminal nerves. Its use as an anesthetic was suggested to him by its hypodermic use in the treatment of malaria. He found that there was no evidence of pain on a second injection in the same area after an interval of 5 minutes. All soluble salts of quinine could be used, but the bichloride was most convenient on account of its greater solubility. Up to the time when he presented his report he had used it in 65 minor operations. He recommended a 1 per cent. solution for local injection, although in his first operations he used a 1½ per cent. and a 2 per cent. strength. For local application to mucous surfaces solutions, varying in strength from 10 per cent. to 20 per cent., were suggested. He obtained a perfect anesthesia which lasted from 4 to 5 hours. His conclusions were: (1) It is efficient in 1 to 2 per cent. solutions. (2) Healing is as rapid as with any other local anesthetic. (3) It is safer than any other local anesthetic of anything like equal efficiency. (4) Solutions can be kept in stock and boiled repeatedly without deteriorating. (5) It is much less expensive than any of the more dangerous drugs used for local anesthesia. (6) It is neither patented nor proprietary. (7) It can be obtained almost anywhere. (8) It is efficient when applied in 15 to 20 per cent. solutions to raw surfaces on cotton pledgets. (9) The anesthesia lasts from 1 to 6 hours.

Following the report of Dr. Thibault, its use for tonsillectomies was recommended by Dr. E. J. Brown.

The most complete report to date, however, was made in October, 1909, by Drs. Hertzler, Brewster, and Rogers. They reported that a ½ per cent. and a 1 per cent. solution produced a perfect anesthesia which lasted from 4 to 5 days; after use of the ½ per cent. strength sensation was not restored to any extent for 10 days, and with the 1 per cent. solution sensation was not completely restored after 2 weeks, and at no time was there the least pain. In some cases they found the edge of the wound indurated and thickened. The thickening appeared to be due to cellular infiltration. By experiment it was found that the exudate began to appear in a few minutes and its was determined that the amount of exudate depended on the strength of the solution. A ½ per cent. strength showed less exudate than a 1 per cent., and in a ¼ per cent. only traces could be discovered. They stated that by adding physiological salt solution the induration was little or not at all marked, but the duration of the anesthesia was much lessened. They recommended ¼ per cent. to be the strength most desirable for anesthesia in the class of work where speedy primary union of the skin is desirable, and where duration of the anesthesia beyond several hours is not required. Their conclusions were: (1) It is absolutely safe; (2) Duration; the after-pain in certain wounds is avoided; (3) It has a superior hemostatic effect.

Hertzler and co-workers observed that the weaker the solution the less the induration noted on palpation. In the use of the ¼ and 1/6 per cent. solution scarcely any was noted. The stronger solution is desirable because of the hemostatic effect exercised by the fibrinous exudate. In regions where primary union is not necessary, they found the stronger solutions to be most satisfactory. Hertzler desires particularly to emphasize the value of this anesthetic in two operations: (1) In operations around the anus (fistulas and hemorrhoids), and (2) in tonsillectomies.

Hirschman used this anesthetic quite extensively in anorectal surgery. For hemorrhoids he injected 1 ounce of a 1 per cent. solution and waited 10 minutes. He says the advantages over any of the other anesthetic drugs may be summed up as follows: (1) It is soluble in water. (2 It can be sterilized. (3) It is equal to cocaine in anesthetic power. (4) It is absolutely non-toxic. (5) It has a pronounced hemostatic action. (6) Post-operative anesthesia lasts from 4 hours to several days. (7) It is inexpensive and almost always available.

Graham, who has used it quite extensively, advises a 1 per cent. solution, and says that it should never be used intravenously. He used a larger quantity of it than of cocaine. He boiled the solution before using, and gave hypodermics of 50, of 55, and of 80 minims.

Nicholson used it in 30 cases. All were satisfactory except one. He mentions the following advantages: (1) Its solubility; (2) it admits of sterilization; (3) it has superior anesthetic properties; (4) it has pronounced hemostatic action; (5) duration of post-operative anesthesia; (6) it is non-toxic; (7) it is inexpensive.

The only report from Europe which I have been able to find is the one of Dr. Gaudier of Paris. He performed with this method numerous operations on the nose, superficial tumors, and other lesions in mucous membranes. It was his experience that this method of anesthesia did not prevent local hemorrhage, and that the oozing recommenced at the slightest excuse, when the dressings were changed. He stated that the anesthesia induced was more slightly localized than with cocaine, and lasted longer. He was able to renew the compressing dressings 5 hours afterwards without pain. The reduction of sensibility persisted on an average fully 3 days. This property he added, may commend this method particularly for treatment of fractures. Cicatrization, however, seemed to him to be a little retarded, the wound not healing quite as quickly as with cocaine. The anesthesia induced did not develop as rapidly as cocaine anesthesia, and was not quite so profound, but it lasted much longer.

Case I—*Removal of Lipoma.*—A. L., age forty-one. A 1 per cent. solution was used. Anesthesia was complete in 7 minutes. No pain and very slight hemorrhage. Redressings were continued at intervals for 14 days, at the end of which time the wound was entirely healed, and no pain was felt at any time during the redressings. A slight induration was noted on the day following the operation. This had entirely disappeared at the end of 3 months.

Case II—*Removal of Fibroma.*—A. P., male, age thirty-six. A 1 per cent. solution was used. There was much pain and profuse hemorrhage. The pain could be accounted for by the fact that the operation was commenced at the end of 2 minutes, before the part was completely anesthetized. Not all the tumor was removed because of the hemorrhage, and because of the restlessness and resistance of the patient, as well as the difficulty experienced in separating the fibrous tissue. Some pain was noted when succeeding dressings were done, and there was some induration. The dressing was removed by the patient, and the wound became infected and did not heal for 3 weeks. When examined 3 months later a slight depression was noticed where the tumor was removed, and there was still some thickening about the site of the operation, but some of this may be accounted for by the fact that a small part of the tumor had not been removed.

Case III—*Removal of Lipoma.*—A. J., male, age thirty-four. A 1 per cent. solution was used: The anesthesia was complete in 7 minutes. No pain; very slight hemorrhage; no pain on subsequent dressings. Wound healed in 14 days. There was a slight induration following the operation, but at the end of 3 months this had entirely disappeared.

Case IV—*Circumcision for advanced phymosis.*—A. B. C., age twenty-seven. A 1 per cent. solution was used. Some pain. The anesthetic did not prove very effective in this case, probably because the incision was made before the part was thoroughly anesthetized. The latter part of the operation, however, did not seem to give the patient much pain and on the whole, he bore the operation well. The parts seemed to be thoroughly anesthetized 6 minutes after injection. There was very little hemorrhage, although the dorsal vein and its branches were quite large. The wound was dressed the following day and the patient claimed to feel no pain whatever. The dressings were reapplied on alternate days for about 16 days, and at the end of this period the wound was entirely healed, the patient feeling no pain at any time during the dressings. There was a slight induration at the frenum, but this gradually disappeared.

Case V—*Removal of two Lipomas.*—J. R., age forty-four, male. A 1 per cent. solution was used. Complete anesthesia in 6 minutes. There was only a slight hemorrhage, and no pain. At the end of 16 days both incisions were entirely healed, and the redressings at intervals during this period caused no pain. No induration remained after the healing of the wounds.

Case VI—*Removal of Lipoma.*—J. G., age thirty-four, male. A 1 per cent. solution was used. Complete anesthesia at the end of 8 minutes. No pain. Very slight hemorrhage. Wound completely healed on twelfth day after operation. No pain when redressings were applied. A slight induration was present 3 months after operation. I did not have an opportunity to see this patient after that time.

Case VI.—*Circumcision.*—P. F., age thirty-eight. A 1 per cent. solution was used. Moderate hemorrhage and slight pain. Operation was commenced 8 minutes after solution was injected. The day after the operation the patient removed the dressing and the wound became infected, and it was 15 days before it entirely healed, but during the redressings there was no pain. There was some induration following the operation, but this had entirely disappeared at the end of 3 months.

Case VIII—*Circumcision.*—J. W., age twenty-nine. A 1 per cent. solution was used. Complete anesthesia in 8 minutes. No pain. Very slight hemorrhage. Wound entirely healed at the end of 9 days. No pain during the several redressings. Two months after the operation there was a slight induration, but this disappeared later.

Case IX—*Removal of Lipoma.*—G. L. age forty, male. A 1 per cent. solution was used. At the end of 6 minutes the part was completely anesthetized. No pain, hemorrhage slight. Redressings were applied at intervals until the end of 14 days, when the wound was entirely healed. There was no pain during the redressings. One month after the operation there was a very slight induration present.

Case X—*Incision of Boil*—A. E. G., age twenty-two, male. A 1 per cent. solution was used. After a wait of 8 minutes the incision was made. There was a very slight hemorrhage and slight pain. Pressure from dressings caused some pain, particularly on the fourth day after the operation.

In order that I may not be misunderstood in my statement in regard to there being no pain when redressings were applied, a few words about my method of surgical dressings are necessary. Immediately after the operation wet bichloride dressings were applied, and the same on the second day; after which I used aristol as a dry dressing. If necessary the bichloride dressings were continued for a longer period.

Conclusions.—(1) In a few of my first cases I commenced my operation before the part was completely anesthetized. I would suggest that an interval elapse of at least 10 to 20 minutes. (2) Post-operative anesthesia lasted on an average 3 days. (3) No dermatitis followed its use. (4) It is less expensive than cocaine. (5) It is soluble in both alcohol and water. (6) It has a very decided hemostatic effect. (7) There has been some induration in the majority of my cases. At the end of 3 months this had disappeared in nearly all of them. (8) Some cases have been reported in which it was successfully used in major operations. Thus far I have used it only in minor operations. (9) Any operation usually done with cocaine can be done with this anesthetic. The technique is precisely the same.

Transmission of Tuberculosis.—R. Michaelis, basing his conclusions upon his observations as a country practitioner, which enabled him to study family conditions, states his belief that aerogenous and enterogenous infection in tuberculosis play but a small rôle, while geneogenous infection (Baumgarten), *i.e.* family predisposition, plays a leading rôle.—*Deutsche militärärztliche Zeitschrift.*

PSYCHIC INDIGESTION: A STUDY.

By GEO. M. NILES, M.D.

ATLANTA, GA.

The various disturbances of digestion and nutrition due to psychic disquietude are just beginning to receive the attention they merit. Too often have the manifestations of an upset stomach, of faulty secretion of the digestive glands, of inefficient intestinal peristalsis, or of inadequate elimination been combated in a hammer-and-tongs fashion, with never a thought for the nearly intangible, but no less real, underlying psychic cause.

"Nutritional neurasthenia," "Americanitis," "Morbus strenuosus" and other catchy phrases might lead one to surmise that this were a modern disease, an outcropping of twentieth century civilization, and one of which we should be mournfully proud. Psychic indigestion is by no means a recent discovery, but belongs to that category which the man of wisdom had in mind when he remarked "There is no new thing under the sun." Further than that he recognized specifically the influence of the emotions on the nutritional processes of the human body, for in Ecclesiastes we find that "A merry heart doeth good like medicine," and also "Better a dinner of herbs where love is than a stalled ox and hatred therewith." I might also mention a familiar example in Semitic history—Job, with his cell-exhaustion from mental strain, his autoinfection, and consequent malassimilation.

The mechanical functions of the stomach and intestines, as well as the chemical properties of the various digestive juices, are fairly well understood; and, though many of the intermediate steps in the metabolism of different food elements are unexplained, we can at least calculate their potential value in Nature's constructive housekeeping.

Up to the last few years little weight was accorded the factors responsible for the excitation or inhibition of these juices, apart from the chemical and mechanical. It seems that the well-considered words of old Solomon were unheeded, and for many centuries, in the discussion of physiological digestion as well as of pathological indigestion, the influence of the emotions received scant notice.

Briefly stated, when food is taken the secretion first started is due to the *sensations* of eating and of taste—that is, it is a psychic secretion. The afferent stimuli, whose duty it is to transmit messages of gastronomic interest, originate in the mouth and nostrils; while the efferent path, containing the secretory fibers, is through the vagus nerve. This reflex, like a notice sent to the housewife that "company is coming for dinner," insures the beginning at least of gastric digestion, though its effect is supplemented by further action arising in the stomach itself.

Certain foods contain substances called *secretagogues,* which are capable of causing a flow of gastric juice when taken into the stomach—for instance, meat extractives, meat juices, soups, etc. Other foods, such as bread and white of eggs, are lacking in these ready-formed secretagogues and have practically to depend on the psychic secretions. Experiments have shown that such bland articles, when introduced into the stomach of a dog while his attention is diverted elsewhere, or while he is sleeping, produce no flow of gastric juice and are not digested.

In addition, there are substances generated in the intestinal and pancreatic secretions, designated

by Starling *hormones*, from a Greek word meaning to arouse or excite. These hormones are influenced by the food ingested, varying from a slight to a potent effect, as required.

I might say, without going further into the physiology of digestion, that each of the digestive juices is to a great extent regulated in this manner, both the amount and specific quality being furnished according to the chemical and mechanical needs, these needs being previously interpreted by the psychic sensation evolved. This being understood, it is easy to see how the mental state of an individual may exert a marked effect on both secretion and motility of the digestive organs; how a placid and cheerful frame of mind may aid those organs concerned in the upkeep of the body, or how an unhappy or perturbed mentality may set in motion a long train of stomach and intestinal ills.

The cases of true psychic indigestion are almost invariably found in the middle years of life, among those who think for themselves and others. The nerve centers of young children are less impressionable to emotional excitants; and when the stage of the "lean and slippered pantaloon" has been reached, the waning digestive powers, in their halting efforts to produce needed bodily energy, have no time to play fantastic pranks on the "commissary department." Digestive troubles in these two extremes of life are generally due to dietetic errors, while in old people organic and malignant maladies play an important part.

Seldom do we find psychic indigestion among those who earn their bread by manual toil, except in brief explosions due to some violent mental irritants. The strenuous spirits of both sexes, those on whose metaphorical shoulders and hearts rest the burdens of home or municipality; who keep turning the wheels of religion, state, or commerce—these are the sufferers from this indefinite, but no less actual, disorder. In practically all will be found a strain of neurasthenia, possibly an inherited lack of equilibrium, fostered by an over-busy or unhygienic mode of life. Nor must we forget that a *bona fide* digestive neurosis may be set in motion by some gross error or stress of circumstances, and that this neurosis may persist long after the original cause has disappeared. Then, too, there is that vague group of symptoms, secretory, sensory, and motor combined, which, in the absence of a more exact term, receives that much abused cognomen "nervous dyspepsia"—the bane of both physician and patient. Parenthetically, I might observe that "nervous dyspepsia" is perhaps the most overworked single phrase in medical nomenclature, with the possible exception of "uric acid diathesis."

Instances of psychic indigestion are easy to find both in present and past literature. In Burton's "Anatomy of Melancholy," published in 1621, this occurrence is cited: "A gentlewoman of the same city saw a fat hog cut up, when the entrails were opened, and a noisome savour offended her nose, she much disliked, and would not longer abide; a physician in presence told her, as that hog, so was she, full of filthy excrements, and aggravated the matter by some other loathsome instances, insomuch this nice gentlewoman apprehended it so deeply that she fell forthwith a-vomiting, and was so mightily distempered in mind and body, that with all his art and persuasion, for some months after, he could not restore her to herself again, nor could she forget nor remove the object out of her sight."

In discussing nervous anorexia some months ago, I reported the case of a lady who could not order supplies from the butcher over the 'phone, on account of the mental images produced. When she attempted it she would at once conjure up vivid pictures of gory meat, of raw head and bloody bones, while all the loathsome scenes connected with the shambles would so crowd her seething imagination that she would be at once seized with nausea and vomiting.

To encompass in a few pages the almost bewildering subject of gastrointestinal psychoses is an impossible task. These protean ills tax both the patience and acumen of the most careful physicians, and cannot be dealt with by any "rule of thumb." As Bassler recently said, "When we deal with perverted states in the minds of others, we deal with effects from conception and perception, mental habits, inheritance, and early training, physical and mental environments, and education, hopes, fears, ambitions, disappointments, grief, suspense, and anxiety."

To realize how all of these may affect the body in general and the alimentary tract in particular, one needs only to analyze moments in his own past life, or incidents in the lives of others under his close observation, and, coupled with the enlightening researches of Cannon and Pawlow, he will more nearly appreciate the intimate relationship of the emotions with the digestive processes. I am confident that every one reading this article can recall in his experience some pronounced symptoms of cessation of digestion, as spasms of the cardia or pylorus, manifested by anorexia, nausea, or vomiting, brought on by purely emotional reasons.

The first mental perversion may disturb the stomach, and the perversion of the stomach, in turn, may arouse in the mind greater disturbance; and thus between them, the influence may continue to and fro like a pendulum, until digestion is seriously impaired and functional derangements may merge into organic changes.

Permit a few random illustrations: Hornborg observed a little boy who was exceedingly hungry, but, after waiting until he became so impatient that he cried, when food was offered him no salivary secretion appeared, and he could not swallow except by an effort. Muller reported the case of a young woman whose lover had broken the engagement of marriage. She wept in bitter sorrow for several days, and during that time vomited whatever food she partook.

A number of years ago, when in general practice, I attended a primipara whose husband was a hearty and robust man. He ate a good breakfast, but soon after, on being grieved by her pains and lamentations, vomited the whole meal, nor could he eat again until she was safely delivered. Recently there came under my care for chronic indigestion a married lady, who, up to the death of her only infant, which occurred over a year ago, "never knew she had a stomach," to quote her own words. Treatment proved entirely unsatisfactory, until the prospects of another offspring changed the tenor of her melancholy thoughts, after which she had no further trouble.

That the narration of some disgusting anecdote or the discussion of an unsavory subject during a meal may inhibit the appetite or set up vomiting is of common knowledge, while the salutary effects of pleasant surroundings and the amenities of the table have been written of by myself and others.

A digestive neurosis is a thing of infinite variations. It may change its symptoms from week to week, almost from day to day. It may exhibit a complex group, or may present in some one particular an inexplicable annoying condition. It is well, therefore, before "standing pat" on a diagnosis of psychic indigestion to exhaust every intelligent method of investigation, and by the process of careful exclusion eliminate as far as possible underlying organic lesions. I say *as far as possible*, for in some instances organic disturbances are present either *propter hoc* or *post hoc,* and must be taken into account in the management of a case.

As to the treatment of this series of gastrointestinal psychoses, I can say that it must embrace more hygiene than dietetics, more suggestion than drugs. It is among these patients that the personal equation of the medical attendant counts for much; for the cheery optimist who can instill confidence and hope in doubting and despondent hearts is the one who gets results.

Therapeutic cognizance must be taken of tangible bodily ailments, and appropriate medication has its important place here, as in other more material troubles. He, however, who attempts to reach these shifting and evanescent psychoses by a hidebound system of dietetics, stomachics, digestants, tonics, or any other adventitious aids to digestion will be foredoomed to failure. Along the line of uplifting suggestion the isms and cults have won some of their spectacular victories, and the medical profession has been far too slow to gather from these erratic creeds the few real jewels contained therein.

Another therapeutic measure which often proves of benefit is a radical change of occupation or environment. To send the tired city dweller into the country; to transport the lonely dyspeptic from the farm to the busy turmoil of the city; to take the "indoor man" from his books or counter and put him "on the road"; or to give the worn traveler a quiet occupation, will in many instances change the diseased current of digestive thought, banishing the subjective symptoms, the introspection, the self-analysis, the self-pity. When the minds of these sorrowful invalids are taken from their stomachs; when their daily thought are lifted out from introspective ruts; when their ill-nourished bodies are furnished sufficient food, and their desiccated tissues are laved with an abundance of water —then can the vicious circle be broken and the psychic aids to digestion resume their normal place in the bodily economy.

920-921 Candler Building.

CAN INEBRIATES BE CURED BY PHYSICAL MEANS IN HOSPITALS?

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

SUPERINTENDENT WALNUT LODGE HOSPITAL.

An eminent medical man, in a letter to me, asked this question, and expressed a doubt of the wisdom of the effort to establish a hospital in New York for the physical treatment of inebriates. Evidently he is not convinced of the disease of inebriety, but considers it a moral disorder, which the Church and State are best able to treat. This doubt is entertained by many persons, even in the profession, and unfortunately it will be an obstruction in the efforts to build up an institution, provided for by an act of the Legislature and the appropriation of a large sum of money. The history of the inebriate hospital movement is exceedingly interesting from a medical and psychological point of view.

Notwithstanding over half a century of study and criticism, many of the central facts underlying the disease of inebriety and its treatment are unknown. Inebriates in a general way may be divided into two classes: those who drink at intervals to great excess, and have long or short periods of sobriety; others who drink continuously, taking small quantities at the beginning and later increasing the amount. There comes a time in the history of all these cases when the term "chronicity" can be applied to them, meaning an extreme stage of degeneration, both physical and mental. The particular class which this New York State inebriate hospital is intended to take care of is the chronic cases; men and women who have drunk for years and become incapacitated, non-supporting, and dependent on others. Obviously the State treatment by fines and short terms of imprisonment increases the drink disease and incapacitates the victims to live normally.

This new hospital is intended to gather these incurables on a large farm in the country and concentrate every known means for building up and restoring the diseased conditions of such persons. The question is asked in some circles "What is this hospital going to do? What restoration and cure can be expected?" Whatever the early causes may have been in producing the drink craze, there can be no doubt that the effect of alcohol has been that of continuous toxemia and anesthesia.

States of intoxication produce chemical paralysis of the nerve centers, with derangement of metabolism to the extent of profound collapse and disturbance of the normal functions. Each intoxication has been and is a traumatism from drugs, with suspension, derangement, and change of both functional and organic activities. Absolute recovery from this condition is practically impossible, no matter what the appearances may be. Repeated intoxicants covering a period of years must of necessity be followed by physcological changes and diseased conditions. Some curious studies have been made of the number of intoxications the system will tolerate before final collapse. The results of these studies show great variations, from ten to several hundred before death occurred. Unlike any other poisoning, each drink paroxysm predisposes and favors the return of another one. Like attacks of epilepsy, the desire for drink to the point of intoxication is fostered and increased, notwithstanding the efforts to combat it.

In the second class of inebriates who drink continuously there is profound cumulative depression. The anesthesia of alcohol affects the sensory centers, extending up to the motor centers, and influences the entire organism. This may be slight at first, but the effect of alcohol is continuous and depressing. The fatigue and pain centers are permanently disabled. An organic change of the body is produced. The continuous drinker is profoundly paralyzed, although he does not know it. His conceptions and appreciation of the relations of his own body to the surroundings are altered. He is poisoned, and there are anemia, congestion, and defective nutrition and elimination. Unlike the first class of periodic drinkers, who are convulsive, delirious, and maniacal, those of the second class are melancholic, suicidal, and degenerate.

There are distinct diseases and degenerations in both of these classes, some markedly local. In all there are uniform symptoms of physical and mental defects.

Insanity, criminality, pauperism are all combined. They are amenable to treament, in fact, the more they are diseased the more they are subject to conditions which are controllable by surroundings and scientific means and measures. A workhouse hospital in the country, conducted on a military plan of exact duties and responsibilities with alternate restraint and liberty, with full control over the every-day habits of eating, sleeping, and exercising, is the first requisite. The active cause, spirits, is removed and the deranged metabolism of the body corrected by hydropathic and other means found useful. This, with exercise and nerve rest in stimulating surroundings, constitutes a treatment full of promise. It is practically removing the cause and forcing the patient to live a hygienic, normal life. There must be a recognition of his physical condition and the application of exact means and appliances to correct this. This is the scientific principle of all practical medicine and is not a theory, but a fact which is supported by a very large amount of evidence, which has been accumulating for over half a century.

A large number of private hospitals have demonstrated the curability of many of this class by the simplest means and appliances combined with the best surroundings and mental measures. The quacks, with their secret remedies and boasted claims, add farther evidence. The breaking up of the drink craze and producing a disgust for spirits is a comparatively simple thing, but to build up a degree of vigor and strength that will repel all desire for relief from spirits in the future is a practical promise of a final cure.

Confinement in jails and hospitals where spirits cannot be procured is simply removing certain causes which may be only active or predisposing. If to the jail and hospital can be added sanatorium influences with physical culture, growth, and mental training, a larger field of causes may be removed.

The frequent sneers of medical men that private hospitals are without value because their inmates relapse after treatment are unjust. The hospital may not have recognized that the real condition was not alcohol but some other causes, which could not be reached by their treatment. To expect successful treatment in a few weeks of a disease that has been going on for years is unreasonable; to expect that the subsidence of the drink craze is the cure of the disease is also unreasonable. The private hospitals have proven that the causes of inebriety are very complex and come down from the past generation, and the desire for the anesthesia of spirits is both a symptom and a cause of conditions existing long before.

Appeals to the mind and will power are delusive, because they do not reach far enough back to the real causes. An inebriate clergyman, whose drinking life and efforts to recover were the subject of intense anxiety and concern, was found at his death to have been suffering from the pressure of a fragment of a bullet on the brain received during his war experience. This was the exciting cause of his inebriety. Thus blows on the head, injuries, diseases, and a great variety of distinct physical causes have brought on inebriety, which has disappeared when these causes were recognized and treated.

All hospitals where inebriates are treated with precision have records of similar cases with cures. Innumerable instances occur in which change of surroundings and conditions, with and without medical advice, have resulted in permanent restoration and recovery.

It is a well recognized fact that the distinct craze for spirits is a symptom which often dies out from causes unknown, evidently due to some physiological change in the brain and nervous system. This accounts for the number of persons who suddenly, and from very trifling causes, lose all desire for spirits and remain temperate for the rest of life. A number of persons ascribe their cure to certain drugs or combinations of remedies that have no particular value. These drugs, when used in other persons, fail and the causes of failure are explained at great length. A physician finding a certain combination of well known drugs to produce a disgust for spirits reasons that this is a specific, yet practical experience in similar conditions fails to confirm this. Statistics of cures covering a year or two of persons who have used these specific drugs are presented as evidence, but this is delusive. A little further examination shows that the percentage of cures is very small. The same active causes when started again will produce the same results. The farce of supposing that chemical means and chemical restraints, in three days or three weeks, will produce a permanent change in the organism and restore the diseased condition is constantly seen in the numerous papers praising this and that method of treatment. Public sentiment gives great credit to the statement of inebriates whose very egotism and dogmatic assertions are suspicious. All this belongs to the empirical stage of the study of this subject. The evidence is unmistakable that inebriety in all stages is curable in the same sense as other diseases. The permanency of the cure is a question to be determined in the coming years.

Almost every private hospital can point out instances of restoration extending over many years, with every promise of permanency. The best statistics from careful authorities show that one in every three persons who are scientifically treated and are not in the extreme chronic stages recover. Every student of the subject realizes the possibilities of more exact care and treatment in better and more perfect surroundings. Frequently persons in extreme chronic conditions come under treatment and make a startling recovery; that is, become restored and remain temperate for life. This approximates a cure and gives clear indications of the possible restoration from larger and better means and methods.

A State hospital, managed on broad scientific lines, combining everything known to be useful in restoring diseased brain and tissue, and forcing the patient to live in conditions of normal health with the best environment, both mental and physical, will do a great work in practically restoring to usefulness a large number of persons who are now burdens to their friends and the community. Such a hospital will combine moral and mental remedies with psychical appliances in the best conditions for permanent impressions and changes. This has been done on a small scale in a great many ways and will be no experiment. Exercise and employment have their value as well as drugs. Environment and stimulating mental atmosphere are as useful as hydropathic measures. All such persons must be treated according to the conditions, and this requires separate study of each patient.

Large palatial buildings are not required to furnish these conditions. Small well-appointed buildings with ample room and methods of separation and segregation are required. Above all, the management must be scientific without theories or preconceived notions. The patients must be treated according to their conditions, and these must be studied and known. The managers of these new hospitals have an opportunity to do original work of greater magnitude and of equal importance to that of the best endowed laboratory in the world. They have an open field, which only a few pioneers have occupied, but never along lines of such magnitude and with such complete appliances.

The first hospital at Binghamton, N. Y., was the great pioneer effort of the world, and its founder, Dr. Turner, was discredited, and yet he was the greatest authority and realized more thoroughly the magnitude and the capacity of the work than anyone up to this time.

A number of very enthusiastic men in Europe are struggling with this problem. Twenty-two state institutions under government control of a medical inspector are working in England. The reports of the inspector give some idea of the difficulties, but are full of the most hopeful promises, but none of them have hardly touched the subject yet.

As New York State originated the first institution in the world, it has now an opportunity, in the second effort, to build a pioneer hospital to do pioneer work that shall be the model for the world and revolutionize the present shameful methods of destroying the inebriate in an effort to cure him.

An answer to the question "Are inebriates curable?" can be found in the evidence which has been accumulating for a period of fifty years and in the transactions and journal of The American Society for the Study of Alcohol and Other Narcotics, which society has been in existence over thirty years.

Still further evidence can be found in the dozen volumes on "The Disease of Inebriety" published in this country and England, and the reports of over fifty different hospitals in all parts of the world where inebriety has been made a study.

The medical man who doubts the practical nature of this new hospital and its efficacy to restore the inebriate is belated in his knowledge of the subject. This great hospital which is now projected will be an assured success dependent entirely upon the wisdom of its managers, and with the data at their command, if studied, there can be no question of its future.

FOREIGN BODIES IN THE LUNG SIMULATING PLEURAL EFFUSION.

By JOHN W. BOYCE, M.D.,

PITTSBURG, PA.

Scattered through periodical literature are a number of reports of cases of supposed consumption, in which later an unsuspected foreign body worked its way out through the side or was coughed up with resulting cure. In several instances since the discovery of the *x*-ray the condition has been diagnosed in time to permit of surgical intervention with the happiest results. Such reports will doubtless multiply as the internist comes to appreciate the fact that the ray is an indispensable adjunct in the diagnosis of chest disease.

In the older books on physical diagnosis there is considerable discussion of the physical signs of foreign bodies in the lung or bronchus. The statements made, however, seem to have been mere theoretical assumption and are not borne out by such cases as I have had the opportunity of observing. In most cases I have found only the physical signs of a consecutive, diffuse, purulent bronchitis, and the physical signs have been of rather less value in diagnosis than the presence of purulent, blood-stained sputum, free from tubercle bacilli. In the four cases herewith reported the physical signs were peculiar and the *x*-ray picture was made with no anticipation of what it was going to reveal.

Case I.—Several years ago Dr. Ingals of Chicago diagnosed a foreign body in the lung in a patient who had previously been tapped for pleural effusion. The physical signs, as reported, justified not only tapping but in my opinion actual exploratory incision. It needed the authority of Ingals to convince me that the diagnosis was correct. A year or two later, however, through the courtesy of Dr. Hubbard of Toledo, I had the opportunity of examining a case where an upholsterer's tack had been imbedded in the left bronchus just below the upper lobe branch for several years. The physical signs were here identical with those reported in Ingals' case. Over the lower two-thirds of that side of the chest the percussion note was dull or flat, voice and breath sounds absent. Over the upper lobe of the lung there was impaired resonance, the note being high pitched and approaching tympanitic quality, breath sounds harsh, voice conduction and vocal fremitus slightly increased.

The next two cases I saw with Dr. Chevalier Jackson, who removed the foreign bodies through the bronchoscope.

Case II.—J. A., aged 23, "swallowed" a brass-headed tack seven years ago, and spent a week in a hospital, where she was assured that the foreign body would pass harmlessly. From this I infer that she had no respiratory symptoms at that time. For over five years she enjoyed fair health, though on questioning she admits that she had frequent colds. In fact, she had a cough every winter. About a year and a half ago she began to cough, with foul smelling, mucopurulent expectoration. At times she was worse, with irregular temperature and rapid loss of weight. The cough and expectoration were constant. Needless to say she was treated by several different physicians for tuberculosis. In the spring of this year she entered Jefferson Hospital, Philadelphia, on the service of Dr. J. Solis-Cohen. He found both apices free from disease. The only physical signs were some impairment of resonance at the right base with diminished voice and breath sounds. These signs were not sufficiently marked to justify the diagnosis of pleural effusion, but in the hands of a less alert observer would doubtless have gone for an ordinary case of thickened pleura. A stereoscopic plate by Dr. Manges showed plainly the long-forgotten brass tack below and behind the right bronchial trunk. Removal of this body through the bronchoscope will doubtless be reported in detail by Dr. Jackson, as the technique was interesting and marked a distinct advance in bronchoscopy, but the simulation of the signs of a pleural condition is all that concerns us for the present.

Case III.—B. C., aged 19; has suffered impaired health for two years. Nine years ago an operation was performed for drainage of an empyema.

Since that time has been treated by residence in Arizona and other favorable climates, but has continually been in poor health. Is under weight, pigeon-breasted, has marked dextrocardia; suffered continually from cough, usually with purulent sputum, frequently pink stained, and occasionally foul smelling. Frequently has a low, irregular temperature very suggestive of tubercle, but the sputum examinations are always negative in this respect. Apices free from disease. The physical signs are confined to the base of the right lung and have been attributed to the former empyema. The case recently came under the observation of Dr. James F. Edgerton of New York, who considered this an insufficient explanation and accordingly had an *x*-ray examination made by Dr. Louis G. Cole. The plates showed the dextrocardia due to fibrous contraction at the right base and also a small lead collar button which Dr. Cole located, by triangulation, midway between the angle of the scapula and the spine, 2½ inches from the posterior wall of the chest. At this point I could find no abnormal signs, but below it extending to the edge of the lung both breath and voice sounds were increased with a suggestion of amphoric breathing and whispered pectoriloquy. No change in percussion note. I was unable to demonstrate either tympany, cracked-pot note, or Wintrich's change of tone when the mouth was open. Bronchoscopy by Dr. Jackson showed a cavity extending well down to the base of the lung at the back. The foreign body was dug from a mass of exuberant granulations, at the point of communication between the bronchus and the cavity.

On reviewing the case it occurred to me that the supposed empyema of nine years was diagnosed on the strength of just such physical signs as I have noted in the preceding cases. On inquiry I found that at the time of the operation only a very small amount of pus was obtained and that the cavity never drained well. It seems to me not an unwarranted assumption that the signs were given by a pulmonary abscess formed behind a plugged bronchial tube and the pus obtained at operation came from the substance of the lung. This theory was confirmed as a possibility by Dr. Singleton Belt, the family physician, who had been present at the operation.

My own theory as to the production of these signs is that the foreign body and the resultant mucosal swelling completely plug the bronchial tubes and the secretion fills not only the tubules but also the alveoli, giving the lung the physical characteristics of a sac full of fluid. Whether this explanation will be confirmed or not, it seems important to record the fact that symptoms of consumption and physical signs suggesting pleural effusion or thickening may be due to a forgotten foreign body.

NORMAL PREGNANCY FOLLOWING TWO ECTOPICS.

By FORBES R. McCREERY, M.D.,

NEW YORK.

Mrs. H., æt. 31, II-para, seen July 14, 1902. She was said to have had a miscarriage one month ago. Two weeks ago sudden severe abdominal pains appeared, and since then she has had some pain and tenderness with slight fever. Examination showed the uterus forward and to the right, moderately enlarged. There was a mass in the cul-de-sac reaching almost to the umbilicus.

On July 15 the uterus was curetted and shreds resembling the decidua were removed. Posterior vaginal section was performed and about one quart of blood clots and fluid blood was evacuated. Gauze drainage was instituted. Convalescence was satisfactory.

On July 12, 1905, the patient reported that her last menses was on May 15 to 18. She had had pain in the left side at intervals and a slight flow since June 30; an abundant flow occurred from July 5 to 11. Examination at this time showed a boggy tumor the size of a lemon behind the uterus.

On July 13 the abdomen was opened through the left rectus sheath. A little free blood was found among the coils of intestines. The right tube and ovary were normal. The left tube was enlarged and bound down by old adhesion in the cul-de-sac. I removed the left tube and ovary. The tube was dilated to the size of a small lemon and contained an unruptured gestation sac through which the fetus could be plainly seen. Convalescence was normal.

On December 13, 1910, the woman was delivered of a healthy male child.

123 East Fortieth Street.

Diagnosis of Abortive Types of Whooping Cough.—H. Delcourt finds that these cases, which are quite common, may be diagnosed with the aid of the Bordet-Gengou reaction. The recognition in these cases of the Bordet-Gengou bacillus is not available in a general practice.—*Archives de Médecine des Enfants.*

Osteitis Deformans.—E. Corner reports a case which illustrates the influence of previous fractures of the patella *before* the onset of osteitis deformans. The patellae were enormously enlarged. The patient was a man aged 38, whose left patella was broken and wired fourteen years ago. The right patella was broken seven years ago and wired. The present trouble (the osteitis) started "months ago," but was not sufficiently bad to make the man take heed of it until six to eight months ago. The osteitis has caused great enlargement of the previously fractured patellae.—*Proceedings of the Royal Society of Medicine.*

Gastric Syphilis.—Albert Mathieu says that cases of gastric syphilis are not rare when they are carefully looked for, and in every obscure case of gastric trouble we should think of the possibility of its being of syphilitic origin, and should search for a previous syphilitic history. The lesions may be those of severe chronic gastritis, tumors simulating cancer of the stomach, pyloric stenosis, ulcerations and deformations of the stomach of the nature of biloculation. The author gives the histories of cases of all of these different kinds of lesions produced by syphilis and cured by antisyphilitic treatment. These lesions are characterized by gummatous infiltration with a tendency to sclerotic organization and formation of fibrous tissue at the edges of the gummata. When the gummata have disappeared the fibrous tissue remains as a permanent lesion, rebellious to all treatment. While the gummatous formation remains antisyphilitic treatment causes amelioration of the symptoms, which is remarkable in the rapidity with which it takes place. In forms simulating cancer it is to be noted that cachexia is absent in syphilitic lesions. The reaction of Wassermann is a valuable diagnostic aid in these cases. The author uses the soluble salts of mercury by intramuscular injection. In cases of cancer and ulcer that are not syphilitic iodide of potassium increases the symptoms, while in syphilitic cases its effect is excellent.—*Gazette des Hôpitaux.*

THE EPIDEMIOLOGY AND TREATMENT OF CEREBROSPINAL MENINGITIS.

THE recrudescence during the spring of 1909 of an unusually severe epidemic of meningococcus meningitis in different parts of France, particularly in Paris and its environs, furnished ample opportunity for the study of its mode of spreading, of its occurrence in young infants, of the efficacy of the serum treatment, and of the various accidents associated with this form of therapy. These were the main lines of an investigation conducted by R. Debré, who records his results and observations in an important monograph.* The relation of the "carrier" to the transmission of this disease is brought out with particular emphasis. Nearly one-fourth of all individuals who had lived with meningitis patients harbored the meningococcus in the nasopharynx. The same proportion of "carriers" was found among the pupils in schools that had been attended by the patients. On the other hand, among the attendants in hospitals in which these patients were treated the bacteria carriers were extremely rare. The diffusion of germs was most marked in the families living under bad hygienic conditions. Thee was a notable uniformity in the distribution of the microorganisms in the disease carriers. While the germs were rarely found in the anterior parts of the nasal fossæ, and in the region of the tonsils, they were quite abundant in the posterior portion of the nasal chambers and in the rhinopharynx. Virulent organisms were isolated from healthy subjects, and even the saliva was found contaminated with the meningococcus. Occasionally the bacteria carriers were perfectly healthy, but sometimes they presented the signs of a nasopharyngitis, or symptoms of a mild general meningococcic infection. The bacteria carriers are usually such only for a short time, but occasionally chronic carriers are found who are apparently instrumental in propagating the organism during the periods intervening between epidemics. These observations are in accord with those already known. The important fact is emphasized that there are lacking efficient means of causing the disappearance of the meningococcus from the nasopharynx of the "carriers." This is a problem in hygiene that craves solution.

*"Recherches épidémiologiques, cliniques, et thérapeutiques sur la méningite cérébrospinale." Paris: Félia Alcan, 1911.

The second part of Debré's study deals with the occurrence of cerebrospinal meningitis in young infants, which occurrence, notwithstanding general belief, is relatively common. In these little patients the disease is particularly severe and presents unusual difficulties in diagnosis. The invasion of the disease is very insidious, in sharp contrast to the violent onset in older children and in adults. Generally sopor rather than irritability is the dominant symptom. The associated marked digestive disturbances are a frequent cause of the errors in diagnosis. This initial period is followed by one in which the meningitic symptoms are more clearly defined, but nevertheless they may escape attention. These symptoms are irregularities in the pulse and respiration, increased tension of the anterior fontanelle, and a spinal rigidity. The period of invasion lasts usually more than a week, with remissions and exacerbations, and is followed by the evolution of the characteristic symptoms of the meningitis. Of the different types of the affection studied by the author in young infants, the most interesting was the protracted form associated with cachexia and hydrocephalus.

The serum treatment of meningoccic meningitis has abundantly demonstrated its efficacy. Debré investigated a special phase of the subject, namely, the accidents associated with this method of treatment. These accidents are described as follows: First, there are the well-known phenomena of anaphylaxis that follow the subarachnoid injection of horse-serum, which phenomena are identical with those succeeding the subcutaneous injection of this and other forms of horse-serum. Secondly, there are in addition specific manifestations of injections of the serum into the subarachnoid space, which manifestations assume the character of an exacerbation of the meningitis, from which they can hardly be differentiated. These phenomena are attributed to a localized toxic edema of the meninges at the site of injection. Thirdly, there are observed during the course of the injection of the serum or immediately afterward pronounced signs of collapse which may terminate in death.

These accidents, which fortunately are extremely rare, are attributed not to sudden mechanical changes in the cerebrospinal pressure, nor to the very rapid destruction of a large number of meningococci with the setting free of an excess of endotoxins, but rather to the injection of a heterologous serum. This occurrence is quite rare after subcutaneous injection of a foreign serum, but is more so following the subarachnoid injections. The diffusion of serum from the subarachnoid space into the general circulation is a rapid one. On the other hand if the serum is injected subcutaneously none of it reaches the subarachnoid space. This observation confirms what has already been known as to the futility of employing the antimeningitis serum hypodermically.

The investigations of Debré furnish a valuable contribution to our knowledge of epidemic meningitis and its treatment, and particularly emphasize the dangers lurking in the innocent carriers of the infection.

ANTITYPHOID INOCULATIONS.

The officers and men alike of the entire army of the United States, 76,000 in all, are being inoculated against typhoid fever—that is, all under forty-five years of age. The Secretary of War has submitted himself to vaccination, setting the example. Heretofore it has been optional for an army officer or private whether he would thus be protected; and on that basis 17,000 were inoculated. But now all must submit, by order of Major-General Leonard Wood. Major Russel of the Army Medical School in Washington has prepared the "typhoid prophylactic," which is being distributed to the various forts, posts, and other military communities throughout the United States and its possessions. In something like a few weeks the whole army is expected to be inoculated, and will certainly, within a fortnight thereafter, be immune to typhoid fever. Very little if any inconvenience has been felt; the vaccination is done precisely as against smallpox, in the left forearm, for all the soldiers. In civil life the left-handed man would be inoculated in the right forearm. The experience has been that the soldier loses not a single day's duty, and does not go to bed. He is watched carefully for twenty days and is then declared a typhoid immune. Of course, those who have unmistakably had the disease are not vaccinated. Whatever discomfort there is never lasts beyond forty-eight hours, and it is in general less than that occasioned by vaccinations against smallpox. Our army is by these measures being rid of typhoid fever, up to recent times a far greater destroyer of soldiers than the enemy's sword and missles. For example, during the Spanish war two divisions of the Seventh Army Corps encamped at the time in Florida were submitted to an experiment; the one numbered 10,759 men, the other 12,801. The camp conditions as to sanitation were exactly alike for these two divisions, and the water for both was obtained from artesian wells. None of the officers or men in the smaller division had been inoculated with the typhoid vaccine; it had 2,693 cases and 248 deaths from this disease. In the larger division a majority were inoculated, and it had but a single case of typhoid fever and no death. Except as just stated, little was done in our Spanish war, so that our troops then developed 20,738 typhoid cases, while above four-fifths of our mortality among officers and men was by reason of this disease. During the Boer war the British had 31,000 cases of typhoid fever. The typhoid fever rate in the German army was cut down one-half by vaccinating a portion of the troops in Southwestern Africa in the campaigns against the Hereros in 1904 and 1907. In India in 1908, among 12,000 English troops, one-half were vaccinated; the remaining 6,000, under like conditions, remained unvaccinated; seven times as many among the latter contracted typhoid, and eleven times as many died of it.

Lieut.-Col. J. R. Kean of the Army Medical Corps observed, anent the recent application of this typhoid prophylaxis to our 16,000 troops in Texas, that although this force had been for more than three months exposed to heat, dust, mud flies, and all the other vicissitudes of camp life, only one case of typhoid fever developed up to June last. "The medical authorities of the army," he said, "are much elated at this great feat of preventive medicine, which they hope will bring into common use a procedure of as great sanitary importance to the American people as was the discovery of the method of preventing yellow fever."

Since such immunity against typhoid is obtainable in military camps it ought to be, as Col. Kean suggests in the sentence above quoted, quite as capable of achievement in civil life—especially in large communities. Every urban typhoid epidemic has been succeeded by a secondary epidemic, evolved naturally from it. The secondary phenomena might easily be prevented by prompt inoculation of all those living in and about the affected region. The private practitioner should have at his disposal antityphoid vaccine, quite as he now has this prophylactic means against smallpox; and he should have his patients submit to the use of the former quite as is done now, as a matter of course, in regard to smallpox. If the inoculations are made in the late afternoon it is very likely that any untoward manifestations will have disappeared by the following noon. These inoculations should especially be submitted to by traveling business men who may in the most subtle and inscrutable ways be subjected to this ingestion infection. Typhoid fever is peculiarly a disease of youth and early manhood and womanhood; and it might not be inadvisable for these young men and women who go to college and boarding school to submit to this preventive measure before leaving home. Tourists, vacationists, may not only themselves contract the disease, but, even of more importance from the communal viewpoint, they may become typhoid carriers, introducing the bacillus into regions hitherto exempt. All such should be inoculated. Physicians themselves, nurses, orderlies and hospital helpers should all submit as a matter of course. It is considered that the protection is effective for two years, and that the one inoculation will afford much, though not complete, protection for many years more, perhaps through the remainder of the individual's life.

THE VARIABILITY OF TYPHUS FEVER.

Much interest was aroused last summer by the discussion between Dr. Brill, who described a "disease of unknown origin" which he differentiated from typhoid fever, while declining to admit that it is typhus, and a Russian physician, Dr. Friedmann, whose experience in Russian epidemics led him to declare that "Brill's disease" is nothing less than the exanthematic typhus of Europe modified by American living conditions. One good result of this discussion has been the awakening of American medical men to the fact that typhus may not be such an unknown and impossible disease so far as America is concerned; indeed, that certain eruptive fevers in Central and Southern America are probably very closely related to typhus of Europe, showing only the modifications, such as "Manchuria typhus" shows when compared with typhus in Russia.

The latter country is, perhaps, the best land in which to study typhus fever, for the disease is ever present there. Russian medical literature can thus throw much light on the subject-matter of the New York controversy, especially as this controversy is quite unknown to the Russian physicians, whose statements, therefore, are unbiased. An article by Dr. Verekundoff in *Ruśskii Vrach* for August 6, 1911, is of interest in this relation. He observed an epidemic occurring in 1908 in which sixty cases were treated in the hospital and about as many outside, many of which, though surely typhus fever, differed greatly from the usual type of the disease. These patients complained of headache, especially frontal, severe pains in the legs and arms, dizziness, weakness, and in some cases vomiting. The temperature was quite unlike that of the classical typhus fever; it often showed a gradual step-ladder ascent, such as is frequently seen in typhoid fever; it fell by more or less quick lysis, instead of by the rapid crisis of typhus; it lasted from nine to twenty-one days. The pulse was always somewhat frequent, usually 110 to 120 per minute, and often dicrotic at the end of the disease. The most important irregularity was noted in the rashes accompanying the fever: in twelve cases no rash whatever was noted; in about as many a roseolar or a roseolopetechial rash appeared, not in great abundance, and faded in two or three days; frequently a roseolar rash appeared fairly late in the disease, about the eighth or ninth day and became petechial two or three days later. The spleen was enlarged in all cases. Hyperemia of the conjunctivæ and of the nasopharynx was frequent; tracheitis, laryngitis, and dry bronchitis were also much in evidence. The mortality was 8.33 per cent., and numerous cases of infection from the patients were observed.

It is seen that the epidemic here described has much in common with the disease described by Brill, though in many points, such as mortality, infectiousness, petechial rashes, etc., it answers pretty well the old ideas of typhus fever, the disease of "poverty, hunger, and dirt." Of course, it neither proves nor disproves any theory regarding Brill's disease; what it shows, however, is important, namely, the variability of typhus fever under certain conditions even in the land where the classical type of the disease has always been present. How much change such a disease may undergo by being transplanted to New York is a matter of conjecture.

THE INCREASE OF INSANITY.

In the belief of perhaps the majority of medical men of the present day insanity is steadily increasing. Some hold the view that mental affections are increasing at an exceedingly rapid rate, and that the world is becoming mad; others contend that the situation has been grossly exaggerated and that as a matter of fact the increase is more apparent than real, due to some extent to the more accurate tabulation of the insane which now takes place. The truth, as usual, probably lies between the two extremes. Insanity has increased, but not so largely as the pessimists assert. In any event, it is instructive to consider the opinions of those who have had experience of the question. J. T. Searcy, superintendent of the Alabama Insane Hospital, read before the Medical Association of the State of Alabama at Montgomery in April, 1911, a paper on the subject (*Dietetic and Hygienic Gazette*, September, 1911, in which he showed from statistics that the increase of admissions into the insane hospitals of Alabama during the past ten years was over 45 per cent., while the population of the State increased only 16 per cent. Similar figures from all the States of the Union point to a like increase, and other civilized countries exhibit a somewhat analogous state of affairs. Searcy thinks that there is no alternative to an admission that there is a large gradual increase of persons so mentally deficient and defective that they come within the jurisdiction of State care. Moreover, the writer draws attention to the fact that not only has insanity increased, but the psychoses are more prevalent.

Of course, heredity counts for much in that increase. As a nation becomes more civilized, so it becomes the object to preserve all human life. In the old days, the principle of the survival of the fittest held sway, and the weakly ones were for the most part eliminated. In these days civilization is more tender by far, and lives are now saved to propagate their kind which in former times would have perished in consonance with the stern laws of nature. When all is said that can be said concerning this phase of the matter, however, it must be allowed that heredity does not account for all.

In the opinion of Searcy the abuse of drugs is an important factor in the increase of insanity and psychoses. It is difficult always to distinguish between cause and effect. It may be that the drug taker is invariably a neurasthenic in the first instance, but it is most assuredly true that drug taking increases the neurasthenic tendencies and may lead to more serious mental derangement. The offspring of drug habitués, be the drug alcohol, morphine, or cocaine, come into the world with an unstable nervous temperament and are unduly susceptible to the effects of narcotics.

Artificial Ulcers.

The occurrence of sores self-inflicted for the securing of certain ends and the relationship of such lesions to multiple gangrene of the skin are matters of great interest. Sores have been produced by beggars in connection with their business of imposture, by conscripts and soldiers to evade military service, by hospital patients to secure free board and lodging, by hysterical subjects to obtain sympathy, etc. These lesions are produced by mechanical and especially by chemical means. The peculiar affection known as multiple gangrene of the skin was long regarded by many dermatologists as a matter of artefacts. The point most suggestive of self-infliction is the occurrence of lesions solely upon areas readily accessible to the fingers, and stopping abruptly just at the limits of such access. But it is not always possible to find a motive for such disfigurement, as shown by a case elaborately reported by Goldbach before the Society of Physicians of Charity Hospital, Berlin, (*Berliner klinische Wochenschrift*, August 7). The patient was finally suspected of causing his lesions with sul-

phuric acid, which produced superficial gangrenous areas. He denied the accusation, but admitted it when erysipelas attacked him, only to deny it again after recovery. He had a comfortable home and a hospital sojourn would have been no inducement to him. From the absence of motive the man was held to be insane, although other evidences of mental disorder were seemingly lacking.

Surgical Psychoses.

In a paper read before the Quarterly Conference of the Chief Executive Officers of State Institutions with the Board of Control at Des Moines, Ia., in March, 1911, A. P. Stoner of Des Moines reported two cases of psychoses following surgical operations. The cases occurred in two women, one of whom was operated on for gall-bladder disease and the other for malignant growth affecting the left breast. Both women, after the operation, exhibited symptoms of insanity, but both recovered in a comparatively brief period. Of course, such instances are by no means very uncommon, and Stoner merely calls attention to them in order to arouse fresh interest in an important and instructive class of cases that, in his opinion, have been hitherto much neglected so far as study and clinical reports are concerned.

News of the Week.

Low Death Rate.—The first nine months of 1911 have made a record low death rate for New York City, the rate per thousand being 15.56 and the total number of deaths 58,144, as against 16.27 and 58,631 for the same period of 1910. This rate of 15.56 per thousand is the lowest for the corresponding period since the formation of the greater city in 1898, the nearest approach to it being in 1909, when the rate was 16.06. The average number of deaths in these nine months for the preceding thirteen years was 55,644, giving an average rate of 18.77 per thousand, so that the rate this year is 3.21 below the average. The mortality among infants also showed a decided decrease during this period, the total number of deaths being 11,733, a rate of 124.6 per thousand of infants living under one year of age, while for the same time in 1910 the total number of deaths was 12,920 and the rate 142.3. This practically means a saving of the lives of 142.3 infants, and this is largely due to the decrease in deaths from diarrheal diseases among infants, the rate falling from 44.2 in 1910 to 34.3 in 1911 with an actual decrease of 784 deaths during the nine months. The decrease in the death rate for all ages, gratifying as it is, is not so great, however, as these figures would imply. The population of the city is estimated, for statistical purposes, on the assumption of a regular rate of increase since the last census, but during the recent period of business depression there has been a large exodus of foreign born laborers with a falling off in immigration, so that the actual population is temporarily considerably below the estimate.

Education in Obstetrics.—Dr. Barton Cooke Hirst, professor of obstetrics in the Medical Department of the University of Pennsylvania, has recently addressed a circular letter to the secretaries of the State Examining Boards calling their attention to the inadequacy of the present system of education in obstetrics, and asking that they submit to their boards the question whether evidence of practical training in obstetrics should not be demanded from an applicant for a license to practise medicine. A committee of the American Gynecological Society last year recommended that at least six cases of labor be attended under supervision by each undergraduate student.

Harvey Society.—The second lecture of the Harvey Society will be delivered at the New York Academy of Medicine on Saturday evening, October 14, by Prof. Albrecht Kossel of the University of Heidelberg on the subject, "The Chemical Structure of the Cell."

Blind Students at Cornell.—There are at present in Cornell University, New York, three blind students who are taking the regular courses, one in the agricultural and two in the arts departments. Of the latter one has just entered his senior year with high standing.

The Budget Exhibit.—At the City Budget Exhibit now being held in New York the head of each department is allotted a day on which to explain the needs of his branch of the city's work, and Commissioner Lederle took advantage of Health Day recently to show how he wishes to spend the $4,387,679.25 for which he has asked for 1912. Four fields were enumerated as particularly worthy of extension: Milk depots, child hygiene, and food and milk inspection. For the first, the department asks for $308,890, an increase of $268,890, with which to establish seventy-three milk stations throughout the city. For the division of child hygiene, the amount asked for is $540,558; for food inspection, $297,270, and for milk inspection, $226,345. The total amount asked for is $1,564,178.75 more than was appropriated for 1911. The portion of the Budget Exhibit furnished by the Department of Health has created so much interest that the question of making it permanent is being discussed, and it is possible that the exhibit will be housed in the quarter of the department where it will be shown throughout the year.

National Board of Health.—In addressing the meeting of the National Civic Federation in New York on October 2, Dr. Harvey W. Wiley, chief of the Bureau of Chemistry, again advocated the establishment of a national board of health, with the head of the department in the President's cabinet.

Green Cross Replaces Red.—Pittsburgh physicians are the first to adopt, as a body, the green cross as an emblem of mercy in time of peace, in distinction from the red cross, whose use it is planned to confine to military organizations and to the International Red Cross Society. The green cross flag is to be unfurled at a benefit to be given for the benefit of the Sewickley Valley Hospital, Pittsburgh, on October 14.

Cholera Spreading.—Although the war with Turkey has taken first place in news from Italy, it is reported that the cholera continues in that country apparently unabated, and that it is spreading through Russia and Austria-Hungary as well as in both European and Asiatic Turkey. The quarantine precautions here have been continued without relaxation, but no case has been reported to the Public Health and Marine-Hospital Service on any vessel arriving at a United States port since August 18.

Fines for Impure Food.—In the Court of Special Sessions of New York recently five dealers were fined for selling impure milk and fish and meat unfit for food. The fines ranged from $10 to $100.

Dr. Wiley.—The Michigan Association of Retail Druggists recently adopted resolutions indorsing Dr. H. W. Wiley and pledging its cooperation in the enforcement of the pure food and drugs law. By an official order of Secretary Wilson issued recently the authority of the Pure Food and Drug Board of the Department of Agriculture has been greatly extended, and Dr. R. E. Doolittle of New York has been appointed to serve upon it in place of Solicitor McCabe. The board is given the right to decide, subject to the approval of the secretary, what cases shall be prosecuted, the power of the solicitor being limited to the preparation of such cases for trial.

Street Accidents in New York.—The National Highways Protective Society reports that during the month of September 43 persons were killed and 234 seriously injured in New York City streets as the result of accidents due to vehicular traffic. Of those killed 20 were children under sixteen years of age. Accidents on New York State highways outside of New York City caused 16 deaths and 164 injuries. The record of railroad grade crossings throughout the State for the month shows 7 accidents, in which 3 were killed and 12 injured.

Prof. Silvio Tonnini of the University of Bologna, Italy, arrived in New York on October 5.

Philadelphia Medical Club.—A reception was held on October 6 in honor of the following new incumbents of chairs in the medical department of the University of Pennsylvania: Dr. Edward Marin, surgery; Dr. Alfred Stengel, medicine; Dr. John B. Deaver, practical surgery; Dr. Gwillym G. Davis, orthopedic surgery; Dr. M. B. Hartzell, dermatology; Dr. M. Howard Fussell, applied therapeutics; Dr. Alonzo Englebert Taylor, physiological chemistry; Dr. Richard M. Pearce, research medicine; Dr. A. H. Richards, pharmacology. Addresses were made by the president of the club, Dr. Wm. L. Rodman; by Dr. James W. Holland, dean of Jefferson Medical College, and by the guests of honor.

The French Congress on Surgery.—At the twenty-fourth annual meeting of the French Surgical Society, held in Paris last week, papers were read by Drs. Ernest Laplace of Philadelphia and C. L. Gibson and W. B. Coley of New York.

The Alvarenga Prize of the College of Physicians of Philadelphia has been awarded to Dr. Francis D. Patterson for an essay entitled "The Parathyroid Glandules."

Bequests to Charities.—By the will of the late Mrs. Sarah P. Sears of Waltham, Mass., a bequest of $10,000 is made to the Waltham Hospital.

The Memorial Hospital of New London, Conn., has received from the estate of the late Catherine A. D. Bramble, a sum of money to be known as the Henrietta Dudley Fund, the income of which is to be used for the relief of patients suffering from tuberculosis.

Dr. Andrew H. Woods, assistant neurologist to the Philadelphia General Hospital, and lecturer on neurology at the University of Pennsylvania, has accepted an appointment as vice-president of the Canton Christian College in China, and will shortly leave the country to engage in his new work.

Death of the Original Sherlock Holmes.—Dr. Joseph Bell of Edinburgh, whose death occurred on October 4, was said to have been the original from whom Conan Doyle drew his famous character of Sherlock Holmes. Dr. Bell was born in 1837 and was a professor in Edinburgh when Doyle was a medical student there. He was a man of wonderful observation and would often diagnose a patient's disease before questioning him regarding his previous history. He was also an enthusiast in the study of mysterious crimes and always had a solution of the mystery which seemed to fit the case perfectly.

Dr. Bulkley's Lectures on Skin Diseases.—The governors of the New York Skin and Cancer Hospital announce that Dr. L. Duncan Bulkley will give a thirteenth series of Clinical Lectures on Diseases of the Skin in the out-patient hall of the hospital on Wednesday afternoons, from November 1 to December 20, 1911, at 4.15 o'clock. The course will, as usual, be free to the medical profession.

New York and New England Association of Railway Surgeons.—The twenty-first annual session of this association will be held at the Hotel Astor, New York City, on Thursday, November 16, 1911. A very interesting and attractive program has been arranged. Railway surgeons, attorneys, and officials and all members of the medical profession are cordially invited to attend. The president of the association is Dr. F. A. Goodwin, Binghamton, N. Y.; the corresponding secretary, Dr. George Chaffee, 338 Forty-seventh street, Brooklyn, N. Y.

Obituary Notes.—Dr. Moses Craft Latirop of Dover, N. H., a graduate of the Worcester Medical College in 1852, a surgeon in the United States Army during the Civil War, president of the Dover Medical Society, and vice-president of the New Hampshire State Medical Society, and a member of the American Medical Association, and of the Stafford County Medical Society, died at his home after a short illness on September 28, aged 81 years.

Dr. Frank Byron Flanders of Lawrence, Mass., a graduate of the Harvard University Medical School in 1878, a member of the Massachusetts State and Essex County Medical Societies and of the Lawrence Medical Club, and formerly attending surgeon to the Lawrence General Hospital, died at his home on September 28, aged 61 years.

Dr. Clarence L. Nichols of Portland, Ore., a graduate of the Hahnemann Medical College and Hospital of Philadelphia in 1885, died at his home on September 26, aged 50 years.

Dr. Alfred C. Sherwood of Union City, Pa., a graduate of the Department of the University of Pennsylvania in 1873, died suddenly on September 26, aged 72 years.

Dr. John A. Vieregge of St. Paul, Minn., a graduate of the Hamline University College of Medicine, Minneapolis, in 1888, and a member of the Minnesota State and Ramsey County Medical Societies, died at his home of diabetes on September 17, aged 50 years.

Dr. Alfred J. Inloes of Binghamton, N. Y., a graduate of the Washington University School of Medicine in 1869, died at his home on October 5.

Dr. Charles W. Spayd of Wilkesbarre, Pa., a graduate of the Medical Department of the University of Pennsylvania in 1866, and a former surgeon in the United States Army, died at his home on September 29, aged 70 years.

Dr. Isaac L. Kip of New York, a graduate of the Medical Department of New York University in 1854, and a member of the New York State and County Medical Societies, died at his home on October 6, aged 81 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

PTOMAINE POISONING—STATE INSURANCE BILL, OPPOSING CRITICISMS—TUBERCULOSIS EXHIBITION—ITEMS—OBITUARY.

London, September 22, 1911.

Some recent deaths having been attributed to ptomaine poisoning have given rise to alarm, which has been added to by the newspapers. At present it is tinned foods; "canned," I think you call them, especially salmon, which are under suspicion. The grocers, who are holding an exhibition, are naturally concerned, as any rumor of danger in an article of food stops the sale. Their federation has made a statement that every alleged case of ptomaine poisoning shall be investigated by them, and they have engaged eminent scientists for the purpose. This is certainly better than a mere protest. It is the consumers who must be considered, and the fears expressed have been so many that the Local Government Board has issued a memorandum on the subject. That impresses on the public the importance of securing any remaining portions of food which is supposed to have set up symptoms, as well as samples of similar origin—perishable articles to be preserved in ice pending examination. It is added that cans of canned goods with labels intact should be kept. When circumstances suggest a nonbacterial origin, the Board says samples should be sent forthwith to the public analyst for the district, for it is by no means certain that ptomaines in the sense of alkaloidal substances are present in foods which have caused symptoms, though chemical analysis may be valuable in various respects.

I may remark that alleged food poisoning has sometimes been before the courts. The law holds that the seller is responsible for injury if he supply goods not reasonably fit for their purpose, and, of course, the purpose of purchasing food is to eat. In 1909 a man obtained damages for the loss of his wife through eating bad food, and in 1905 a similar verdict was given in a case of typhoid traced to contaminated milk. For prevention more inspection may be urged. So, too, the public may well be cautioned against keeping canned food after opening, as it takes some days for bacteria to develop.

The National Insurance Bill continues to excite attention in various directions. The Friendly Societies are expressing discontent with a number of its provisions, and some of them are in revolt against the medical arrangements. A conference was held last week of some eighty societies said to represent 300,000 members, at which some speakers indulged in very objectionable remarks. They protested vigorously that the right of appointing their own medical officers was a vital one and that the Health Committees should have no voice as to capitation grants or medical fees. On closely examining the expressions used it appears that the claim to choose the doctor is intended by some of the societies to mean that the appointments should continue to be made on the old plan; that is, by each society as such, which amounts to by its committee. If this were permitted, the control of contract practice would remain as obnoxious as ever.

Now, one of the most important votes of the House of Commons in committee on the bill gave a majority of 387 to 15, placing the administration of medical benefits under the local Health Committees. Further, the free choice of the doctor by the patient was passed *nem. con.* This has been until lately universally understood that each member of a society was to exercise this "free choice" as an individual, and this is what the profession accepted. Efforts are being made to get this decision rescinded, and some societies are trying to induce their medical officers to declare themselves satisfied with present conditions. It is hoped that they will refuse to sign any such specious statements and remain faithful to the mass of the profession which has fought their battle. It is scarcely likely that they can be deceived as to the meaning of the proposals being made to them.

The B. M. A. is sending out a circular to counter the proceedings of the societies which oppose this view, as it would perpetuate and extend "the worst abuses of contract practice."

Mr. Lloyd-George seems to have lost his temper over the question and again resorted to characteristic language. Coupling "Tory and Socialist candidates," he wrote, according to this morning's papers, that they are "deliberately setting themselves by deception to rob the workmen of this country of £17,000,000 to provide for the dark days of sickness." This was part of a letter in support of a candidate and, of course, intended for electioneering purposes. On his return to town it is understood he will see representatives of doctors and the societies jointly. He might do well to invite administrators of the hospitals to an interview, for they are seriously perturbed as to the probable effect of his bill on these institutions. In fact, I learn that most of them continue to receive intimations from their subscribers that if the bill passes they must discontinue their subscriptions.

The greater Friendly Societies are opposed to several other provisions, but as they do not so much concern the profession I need not particularize them.

The tuberculosis exhibition seems to have been successful, for it attracted over 15,000 visitors, and the daily lectures, I am told, were listened to with evident interest by large audiences. Sanatoria were spoken of a good deal and lantern lectures freely employed to demonstrate the treatment. Dr. Paterson, who directs the Frimley Sanatorium, insisted that the social and industrial problem is more important than the medical, for it is the workers who suffer most from the disease on account of unemployment, unwholesome dwellings, semi-starvation, and injurious conditions of labor of certain kinds.

Contradictory statements about cholera in Rome have been freely circulated to the disturbance of intending visitors this season. The official records show that in the week August 28 to September 3 there were 22 cases and 10 deaths. In the whole of Italy there have been, between June 22 and September 3, a total of 10,634 cases, 4,086 being fatal. The total in Rome in that period has been 85 cases.

The Australian Medical Congress was formally opened on Monday. It was expected that 600 Australasian members would attend.

A Dental School is to be established at the London Hospital. The first of the Schorstein lectures will begin there on the 3d prox.

Sir Ronald Ross is to succeed the late Sir R. Boyce on the Advisory Medical and Sanitary Committee for Tropical Africa.

Dr. F. W. Pavy, F.R.S., died on the 19th inst., in his 83d year, and the interment is fixed for today. His name will be familiar to you as one who has held a great position among the physicians of

London for many years, during which he was attached to Guy's Hospital, of which he was, of course, consulting physician. He was a long time lecturer on medicine there. He took his M.D., London, as long ago as 1853. At the Royal College of Physicians he became a Fellow in 1860, was the Harveian orator in 1886, having previously been Goulstonian lecturer (1862-3), and given the Croonian lectures in 1878. A second time he occupied the last named office in 1894. He had become Senior Censor of the College (1891-2). Among other offices filled during his long career were President of the Royal Medical Chirurgical Society and of the Pathological Society, and he was correspondent of several American and European Medical Societies. Of his works the volume on diabetes takes precedence, and this subject occupied him all through his life, and its various aspects are considered in many other books and papers, as his treatise on digestion, that on food and diet, that on the carbohydrates and on assimilation. As a clinical teacher he will be gratefully remembered by generations of students now in practice throughout the world. As a consultant he was valued by many others.

Dr. Alexander Gray of Bradford was watching an operation in the Royal Infirmary when he was taken suddenly ill and died in a short time. He had reached an advanced age, but was still active and had paid a number of visits during the day. He took M.B. and C.M., Glasgow, in 1878.

The death has occurred of Dr. Walter Akins Grogono at the age of 62. He was a well-known old London Hospital student, who qualified in 1872, and had been practising in Stratford ever since. He was for many years district medical officer and public vaccinator. Besides the London College of Surgeons, he took both the Edinburgh colleges. For some time he was surgeon and then senior of the West Ham Hospital.

Dr. H. R. Dew, consulting surgeon to Bristol Eye Hospital, and surgeon to other institutions in Bristol, died on September 7, aged 78. He was formerly in the army, and served through the Crimean War, where he was staff surgeon to Lord Raglan. On retiring from the army he settled at Bristol. He qualified in 1855.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

SOCIETY FOR THE PREVENTION OF SEXUAL DISEASES—SEXUAL ABSTINENCE AND ITS EFFECT UPON HEALTH—STATUTORY PROHIBITION OF PROPHYLACTIC MEASURES—ANTITUBERCULOSIS COMMITTEE—PROTECTION OF THE YOUNG FROM TUBERCULOSIS.

BERLIN, September 15, 1911.

AMONG the various congresses whose sessions have been held during the past summer may be mentioned the eighth annual meeting of the German Society for the Prevention of Sexual Diseases, and the fifteenth annual meeting of the German Central Antituberculosis Committee. A short report of these two meetings may be of interest.

Sexual abstinence and its effect upon health was the chief topic of discussion at the first of the above congresses held in Dresden. Professor Eulenburg emphasized the point that in former discussions on this subject too much consideration has been given to the male aspect of the problem. Like in all other medical questions, the fundamental factors have concerned individuality. These factors are sex, age, character, education, and environment. These are factors of importance. Particularly to the female is the question of sexual abstinence of considerable moment. In the healthy youth of both sexes, until about the middle of the twenties, total abstinence from sexual gratification, at any rate amid the climatic, racial, hygienic, and social conditions prevailing among us, is compatible with the maintenance of perfect health. According to the speaker's investigations, 5 per cent. of the students are abstinent. In fully developed adult life sexual abstinence causes a certain degree of abnormality, which appears earlier in women than in men. The psychic development becomes onesided, and there appear anxiety neuroses, sexual neurasthenias, hysterias, and even pronounced psychoses. Organic disorders, such as myomata, endometritis, and carcinoma, can not be regarded as consequences of sexual abstinence. A transient sexual abstinence is harmless to a normal constitution, but persistent or lifelong abstinence, particularly in women, is quite harmful. The succeeding speaker, Professor Touton of Wiesbaden, mentioned among the consequences of sexual abstinence the following: orchitis, epididymitis, hydrocele, varicocele, prostatic hypertrophy and testicular atrophy. The sequelae of abstinence appear only in neuropathic individuals, particularly if the abstinence follows a period of excessive sexual indulgence or of onanism. Impotence does not ensue, while weakening of the libido and of the sexual power is only transitory. Healthy individuals engaged in active mental and bodily work can practice abstinence even until late in life without impairment of health. For this reason abstinence is to be strongly recommended to the young. The succeeding discussion brought out support and opposition to these views. Professor Blaschko of Berlin concluded that abstinence presented the ideal of education, but that this ideal was rarely attained by students. The latter were to be made acquainted with the various prophylactic measures. The second topic for discussion was the statutory and judical prohibition of the use of these preventive measures against venereal contagion. Marcuse of Partenkirchen complained that the law and judicial procedure were getting more and more arrayed against those who recommended the use of these measures. Inasmuch as the revised statutes contemplated severer penalties for this supposed offense, there was presented and adopted a resolution as follows: "Punishment should be inflicted only for the furnishing of knowledge that grossly offends decency, or that recommends unnatural practices."

At the annual meeting of the Central Antituberculosis Committee the general secretary, Nietner, presented a report stating that the membership of this committee was 1500; and that in Germany there were in operation 99 public sanatoria with about 1200 beds, and 34 private sanatoria with 2000 beds. For tuberculosis children there were 22 institutions with 1000 beds, and for scrofulous children and those suspected of having tuberculosis 86 institutions with over 8000 beds. In addition there were 99 forest camps which were partly kept open at night.

The protection of the young from tuberculosis was the subject of a symposium, opened by v. Pirquet, who stated that children should be shielded from the form of inhalation infection. This could be achieved by removing the tuberculous individuals from the family. The notification of cases, and the provision of nurses and sanatoria took care

of the tuberculous adults. If these means were not sufficient to free the household of tuberculosis, then the endangered children should be taken away and placed in healthy families or in institutions. The question was still to be decided whether among children of school age the infection was to be avoided or was to be welcomed as a mode of immunization. The solution of this problem could be accomplished through the coöperation of the members of the committee. By the careful observation of children in orphan asylums, and even of adults, with the aid of the cutaneous tuberculin test, and by segregation of the suspicious cases, there could be gathered in certain places for observation a number of individuals who would be free from tuberculosis. After many years of observation these individuals would furnish material for the solution of many important problems in tuberculosis research. Krautwig of Cologne remarked that the need was being more and more recognized by the members that greater attention than hitherto should be paid to the subject of tuberculosis in children, since these did not come within the operation of the sick benefit societies and insurance companies. Particular attention should be paid to the years preceding the school age, during which years the child did not get the right supervision. Kirchner of Berlin pointed out the importance of this subject when he stated that the children have not shared in the general reduction of mortality from tuberculosis. In the years between ten and fifteen the mortality has even increased.

OUR CANADIAN LETTER.

(From Our Regular Correspondent.)

THE PUBLIC HEALTH SECTION OF THE CANADIAN NATIONAL EXHIBITION HELD IN TORONTO—REPORT OF SPECIAL COMMISSION ON MEDICAL INSPECTION OF SCHOOLS IN CANADA—DEATH OF KING COOK, OF THE MEDICAL DEPARTMENT OF M'GILL UNIVERSITY, MONTREAL—THE CONFERENCE OF CANADIAN CHARITIES AND CORRECTIONS HOSPITAL IN TORONTO—CENSUS STATISTICS—RABIES IN ONTARIO AGAIN—REGULATION OF ONTARIO PROVINCIAL BOARD OF HEALTH TO PREVENT THE POLLUTION OF WATER.

MONTREAL, October 3, 1911.

THE Canadian National Exhibition, which is held yearly in Toronto, and which incidentally is the best annual exhibition of the world, has had for some years many exhibits of great sanitary interest. For example, its milk exhibits have shown year by year the progress made in safeguarding milk from the farm to the consumer. This year, however, for the first time the Toronto Exhibition had a public health section. The initiation of this new departure was due to the Ontario Board of Health, and mainly, of course, to its chief officer, Dr. J. W. S. McCullogh. The interest manifested in this exhibit by the visitors to the exhibition was quite remarkable, and was a significant sign of the times. The ordinary citizen is becoming aware of the value of preventive medicine and is beginning to take an intelligent interest in the subject. Sanitary or public health matters in Canada, as elsewhere, have within the past few years made great strides, but educative measures are needed to cause the people at large to apprehend and appreciate the various preventive measures which are being put forth nowadays. The public health exhibit at Toronto was inaugurated with this end in view. The exhibit is a further development of the traveling tuberculosis exhibit instituted by the board during the past few years. This year for the first time it embraced a large variety of subjects relating to public health, and it is the intention of the board to continue this educational feature upon a larger scale. The space allotted to the exhibit was very limited, but even under these unfortunate conditions the display was striking. The Provincial Board of Health showed a very fine collection of handsomely mounted photographs of sanatoria in Great Britain, Germany, Scandinavia, United States and Canada with plans of others—models of tents, sanatoria and shacks for the care of consumptives. The Toronto Health Department had a good exhibit. However, there were three exhibits which stood out prominently—the charts of the American Association for the Conservation of Vision; the exhibit of the American Association for the Prevention of Infant Mortality, and the various charts, banners and the mechanical models lent by the Department of Health, Chicago. The latter exhibit was in charge of Dr. C. St. Clair Drake, the designer of the models. The first illustrated infant mortality. Three thousand five hundred dolls affixed to the walls represented the babies who died from preventable diseases in Chicago during last year. In front of this was a revolving cylinder operated by clockwork, in which a number of larger dolls were continually appearing, the head of every fourth one of which was chopped off by the Angel of Death who stood above. Another model illustrated ventilation. Two rooms of the same size were represented in which were dolls in tiny beds. At the ordinary breathing rate by means of an ingenious contrivance vapor was seen to issue from the nose of the dolls. In one room which had its doors and windows open the atmosphere remained clear. In the other room, without ventilation, the air was soon quite murky. These models excited great interest and proved the truth of the argument that out-of-the-way methods are necessary to attract the attention of the public. On the whole the public health section at the Toronto exhibit was a great success, and reflected much credit on Dr. McCullogh, who was mainly responsible for its direction and arrangement. The report of the Special Committee on Medical Inspection of Schools in Canada, 1910-1911, has been issued recently. The recommendations of the committee are as follows: A. Organization: Three things are necessary and desirable—1. Governmental recognition. Organization under an official medical expert directly responsible to the provincial government. 2. Coördination of the department with the provincial board of health. 3. Professional control. No one but a physician of high professional standing and culture and able to avail himself to the utmost of all other agencies and organizations can do this work. B. Extension. It is recommended by the committee to extend the work throughout Canada so that deficient children or afflicted children shall be taught, whenever possible, to earn their own living in order that they will not be a burden on the community. The public school at present in Canada gives no help at all to a child who is partially blind or partially deaf. As for the victims of poliomyelitis, now epidemic or threatening to be in certain parts of Canada, and the sufferers from joint tuberculosis steps should be taken to relieve them and assist them to become, at any rate, to some extent self-supporting. The man who had been janitor of the

Medical Department of McGill University for thirty-six years died recently. King Cook, the name by which he was known, was a character and an institution. During the long tenure of his post he had seen several generations of medical students pass, and was by way of being a philosopher and something of a wag. He will be missed more than many with great reputations. The Conference of Canadian Charities and Corrections took place in Hamilton, Ontario, on Sept. 25, Mr. J. Rose Robertson of Toronto, proprietor of the *Evening Telegram*, being in the chair. In the discussion that followed the reading of a paper by Dr. Parry of Hamilton on the care of children, Mr. Robertson gave some of his own experience in this kind of work. He said that it would surprise many people if they knew the true conditions of some of the dairies in Ontario. He also outlined the steps which had been taken in Toronto in order to obtain pure milk. Hospital building and extension proceeds apace. There was a time, and not long ago, when Toronto was almost a byword among the great cities of this continent on account of her inadequacy of hospital accommodations. Now that cause for reproach is being rapidly removed and she bids fair in the not far distant future to be a model for other cities as regards hospital accommodation. The work on the new general hospital is making rapid progress, and the various buildings of the group will soon be ready for the interior work which will be carried on through the winter. The pathological building is expected to be completed during the winter. The surgical wing and medical out-patients' building have been roofed, and the administration building will soon be in a like condition. The buildings for the department of obstetrics and for private wards have not been commenced yet. A feature of the hospital will be four roof gardens on the roof of the main building for the benefit of convalescents.

The census statistics for the whole of Canada will soon be announced. The returns are being awaited from the Yukon and northwest districts. The returns show that Montreal, Toronto, Winnipeg and Ottawa have made remarkable gains. In Ontario the rural population has fallen off, notably in Western Ontario, but this has been partly offset by a tremendous increase of population in Northern Ontario.

Rabies has again exhibited itself among the dogs of Toronto, and the Health Board is likely to take action to prevent its spread. Stringent and comprehensive regulations have been passed by the Ontario Provincial Board of Health for the prevention of the contamination of water. After laying down the regulations for preserving from pollution lakes, rivers, streams or other inland waters, it is enacted that hotels, restaurants, railway trains and depots, boats and other public places which provide a supply of drinking water for the use of the public must safeguard its purity.

Extensive Lupus Erythematosus Associated with Symmetrical Gangrene.—G. W. Dawson reports the case of a man, aged 49, in whom the disease began nearly one year ago, and now there were characteristic patches of the erythematous type on the face, ears, scalp, and back of hands and fingers. For some considerable time he had complained of his fingers going dead and white; actual necrosis had taken place at the end of the right little finger and the lower part of the helix of the right ear; besides these there were several small eschars on the back of the fingers and a few on the nose, leaving slight scarring to mark their site.—*Proceedings of the Royal Society of Medicine.*

Consideration of the Mechanism of Pressure in the Production of Vertigo and Report of Cases. C. J. Blake.
The Value of Lumbar Puncture in the Treatment of Aural Vertigo. J. J. Putnam.
Cancer of the Colon. H. Gage.
Surgical Treatment of Pyloric Stenosis with Report of Cases. S. W. Goddard.
A Reminiscence of My Professional Life. D. W. Cheever.
Bad Reichenhall. A Health Resort of Southern Germany. H. Packard.

Pressure in the Production of Vertigo.—C. J. Blake states that in cases of recurrent vertiginous attack with inadequate evidence of an intralabyrinthine or of an accessible extrinsic pressure factor it seemed desirable to test the effect, upon the line instituted by Babinski, of decrease of intracranial and, correspondingly, of intralabyrinthine pressure by some means which would leave the auditory apparatus intact, an additional incentive to such a series of investigations being previous experiences in disturbances of intralabyrinthine pressure, incident to investigations in regard to the removal of the stapes. Under these considerations, in conjunction with J. J. Putnam, in a series of adult cases in which the extrinsic pressure factor was at a minimum, or absent, lumbar puncture was practised with results thus far sufficiently favorable to warrant a continuation of the investigation. Nine cases are reported in which this procedure was followed. In no instance were there more unfavorable consequences than severe headache of several days' duration in three instances; in all of the cases in which this decompression method of treatment was employed there was a temporary amelioration of the condition, and, in the majority, entire relief from the vertiginous attacks during a period of from a few months to three years, the latter being the major limit of observation.

Lumbar Puncture in the Treatment of Aural Vertigo.—J. J. Putnam states that nine years ago Babinski first called attention to the therapeutic value of the withdrawal of 10 to 20 ccm. of cerebrospinal fluid as a means of treating aural vertigo. The best cases for treatment by lumbar puncture are those in which various tests show that the labyrinthine apparatus is still in a fairly normal state. When the neural degeneration is far advanced the effects of withdrawal of cerebrospinal fluid are less marked at the outset and repetitions of the operation, which in the better cases work well, produce less and less marked results and are eventually of no benefit. The most favorable cases of all are those of pure labyrinthine origin and of relatively short duration. In such cases no great disturbance of hearing is present and especially no serious middle-ear disease.

Cancer of the Colon.—H. Gage notes that the chief anatomical feature of cases of cancer of the colon is the gradual narrowing of the lumen of the gut, and the obvious effect of such a narrowing is an increased constipation. Such a condition, occurring in an individual of suitable age, whose bowels have been in the habit of moving freely and naturally, ought in itself to arouse one's suspicions. If, in addition, it is associated with colicky pain, frequent, small, and unsatisfactory stools, and especially with occasional attacks of diarrhea, the possibility of a malignant stricture should be seriously considered and the importance of an early exploratory incision recognized. Radical removal of the growth should be done early. One is now in a position to follow the lymphatics, which drain the different portions of the gut, into the depths of the mesentery and to remove them, in favorable cases, well beyond the limits of the cancerous invasion. In the carefully selected cases of cancer of the colon operated upon in the Mayos' clinic the mortality was 13 per cent.

Pyloric Stenosis.—S. W. Goddard reports eight cases of pyloric stenosis successfully treated by the performance of a posterior gastroenterostomy.

Reminiscences of Professional Life.—D. W. Cheever continues his article discriptive of medical life during the past fifty years.

Bad Reichenhall.—H. Packard states that the chief therapeutic claims of the little Bavarian village are in the treatment of nontuberculous respiratory difficulties, chronic bronchitis, asthma, etc., although a very high degree of efficiency is demonstrated in cases of neurasthenia and functional heart difficulties.

Apollyons. W. B. Konkle.
A Series of Studies of Nervous Affections in Relation to the Adjustments of the Eyes. G. T. Stevens.
Report of the Psychotherapeutic Clinic at the Cornell Dispensary. H. W. Frink.
Twilight Talks with the Doctor.—VI. G. F. Butler.
Headache. W. Taylor.
Music as a Therapeutic Agent. J. Knott.
Proctoclysis; a New Apparatus for Its Administration. A. E. Isaacs.
An Address to Nurses. J. M. Ferrer.

Apollyons.—W. B. Konkle uses this Greek term in referring to the influences that tend toward the wrecking of the human race. These influences are ease and luxury, overstress of work and of pleasure, dissoluteness and vice, modern war, the tyrannies of fashion as to dress, forms, and usages, and the production of abortion.

Nervous Affections and Adjustments of the Eyes.—G. T. Stevens concludes his series of papers on this subject and states that the heterophoria upon which many nervous manifestations depend may be corrected by the operation for declination, which operation he has called "extendocontraction," of a tendon, and which involves little of the risk attending a tenotomy and involves a minimum of discomfort to the patient.

Psychotherapy.—H. W. Frink reports the results of the work done at the Psychotherapeutic Clinic of the Cornell Dispensary from November, 1909, to July, 1911. Good results were obtained in psychasthenia, hysteria, hypochondriasis, neurotic headache and alcoholism. In sexual neurasthenia, the anxiety neurosis, typical *tic convulsif*, stammering, and in incorrigible children psychic treatment was ineffectual. Formal suggestion was ineffectual in all cases in which only the first stage of hypnosis could be induced. In the three cases in which a complete psychoanalysis was made a cure resulted.

Twilight Talks.—G. F. Butler states that nervous prostration is the disease of rapid civilization. People eat too much and too great a variety of food. They also worry too much—introspection, selfishness, despondency, and hopelessness should be overcome at all hazards.

Headache.—W. Taylor discusses headaches under the following groups, according to the origin of the headaches: Anemic, congestive, toxic, nervous, sympathetic, and organic or structural.

Music in Therapeutics.—J. Knott believes that, in spite of the materialistic tendency of modern science, music still has a place in the art of medicine. The phenomena of perfectly healthy animal existence are guided by rhythmic laws of repetition. The value of music as a power in the social and political life of nations and communities, as well as in the esthetic and temperamental condition and feelings of the individual, has been more or less highly estimated and applied in all parts of the world. The power of music in awakening the emotions is exemplified in the effect of martial strains.

Proctoclysis.—A. E. Isaacs describes a new apparatus for the performance of this procedure.

Address to Nurses.—J. M. Ferrer presents a few parting words of advice to a class of graduating nurses, reminding them of the duties and opportunities of their calling.

A Case of Angiokeratoma. E. H. Trowbridge.
"Singer's Nodule" (Chorditis Nodosa) Removed by Vocal Treatment. F. V. Laurent.
A New Tonsil Scissors. W. S. Windle.

Relationship of Eye and Ear Diseases.—D. Roy believes that every opthalmologist should be competent to make a complete diagnosis of ear diseases. Within the last two or three years the use of nystagmus as an aid to diagnosis in labyrinthine disease has been gaining recognition. A study of the anatomical relations readily explains the possibility of eye diseases arising from ear affections, and frequently ocular paralysis of otitic origin is due to direct transmission of infection from the ear.

Leucocytology of Typhoidal Diseases.—By J. F. Hultgen. (See MEDICAL RECORD, July 1, 1911, page 48.)

Remedies for Animal Parasites.—W. H. Schultz compares the various hookworm remedies as regards their safety and efficiency and finds that thymol, when given under the supervision of a physician, is the best.

Hookworm Disease in California Gold Mines.—E. E. Endicott reports his experiences with this disease in the deep gold mines of California. He believes that this disease is a contributing cause, if not the direct cause, of death in many cases reported as "miner's consumption." As a prophylactic measure the author insists on the provision of proper toilet conveniences in the mines.

Hookworm Disease in California.—H. Gunn notes that of the large number of Porto Ricans that have taken up residence in California one-half are hookworm carriers. Many cases are imported from Hawaii or are brought in by laborers from the Alaska fisheries. In one mine 75 per cent. of the men examined have been found infected.

Brain Surgery.—C. C. Rogers concludes that suspected tumor cases should not be subjected to long-continued antisyphilitic treatment, but a Wassermann test should always be made and, if positive and the gumma is non-vascular, one may conclude that it will not yield to specific treatment until pressure is relieved. The patient should have the benefit of early operation. Intracranial hemorrhage should be evacuated in all cases in which the patient lives long enough to obtain skilled surgical treatment, so as to relieve pressure and prevent infection and adhesions or abscess formation and their consequences. Intracranial pressure should be relieved by decompression to prevent headache, cerebral vomiting, and visual impairment. Three to six weeks is long enough to test the utility of antisyphiltic remedies, and they should be discontinued if not doing good.

Anesthesia from Nitrous Oxide-Oxygen Plus Carbon Dioxide.—E. G. Martin quotes various authorities as to the advantages of nitrous oxide-oxygen anesthesia in cases in which the anesthetic may make the difference between life and death. The newest and best method of

using this form of anesthesia is by rebreathing. The author has been using this method for nearly a year and has observed the rapid pulse become slower with an increase of tension and the respiration also became slower and deeper.

Myotonia Atrophica.—F. Kennedy and C. P. Oberndorf report two cases of this disorder, characterized by weakness and wasting of certain muscles of the face and of the lower limbs with myotonic phenomena in the arm and fingers and depression of deep reflexes.

Quantitative Regulation of the Diet.—By H. D. Arnold and R. C. Larrabee. (See MEDICAL RECORD, July 8, 1911, page 94.)

Hyperthyroidism.—M. F. Porter states that a simple, safe, and effective operation for hyperthyroidism is much to be desired. He believes that the injection of boiling water into the gland would meet the need. His experience with the method up to date has not been sufficient to put it on a firm basis, but he thinks it enough to warrant this belief. Altogether, he has injected boiling water into hyperactive goiters twenty-nine times in four patients. From 40 to 150 minims were injected at each point and from one to three points were injected at each sitting. No untoward results followed the injections in any case but marked improvement always resulted. The treatment is specially adapted to the very mild and very severe cases. The injections should be made within the capsule, avoiding the neighborhood of the parathyroids and recurrent laryngeal nerves and with the same precautions governing the boiling water treatment of angiomata.

Accessory Pancreas.—B. B. Finkelstone reports a case of this condition in which the accessory organ was entirely separate from the normal gland.

Plaster Support for Gastroptosis.—S. D. Dice recommends the use of an abdominal supporter of zinc oxide adhesive plaster on moleskin.

Operator's Table.—L. W. Dean describes a table that he has designed, one that would serve equally well for cataract operations, brain surgery, mastoid operations, throat work, laryngotomy, or bronchoscopy.

Traumatic Mitral Stenosis.—D. Riesman reports a case of mitral stenosis which he believes was the direct result of violent strain. The primary lesion was either a rupture of one of the more important chordæ tendineæ or more likely a hemorrhage into the valvular tissues with later organization and contraction.

Malta Fever in Texas.—E. R. Gentry and T. L. Ferenbaugh state that in 25 of 128 goats examined 19.4 per cent. gave a positive agglutination test for *M. melitensis*. All human cases reported gave a history of association with the goat-raising business and six were drinkers of goat's milk. The factor of dust infection must also be considered.

Hydrophobia.—A. M. Stimson describes the measures that are necessary for the prevention and control of this disease in the human subject.

Angiokeratoma.—E. H. Trowbridge reports a case of this condition affecting the scrotum.

Singer's Nodule.—F. V. Laurent emphasizes the fact that the main treatment of chorditis nodosa is teaching the patient to use the voice and respiratory apparatus properly. This appears to be a much more satisfactory method than operative measures, as, in the latter case, the node will probably reappear in time, while if the patient has learned to use the voice properly, the cause is removed and there is no danger of recurrence.

Tonsil Scissors.—W. S. Windle has devised a new instrument with the following features: 1. The cutting edge of one blade is serrated and the other smooth; this facilitates the cutting of soft, slippery tissue. 2. The outer edge of each blade is wave-like in outline and beveled to a dull knife edge; this serves as a dissector.

A New Thermotherapeutic Method in Gynecological Cases. S. Flatau.
A Case of Myeloid Leucemia with Chylous Ascites. H. S. Furness and G. F. Stebbing.

Extensive Excision of Colon and Ileum.—A. E. Barker states that the removal of long tracts of the large intestine for malignant and other diseases such as tubercle and actinomycosis is now a common operation and one giving excellent results, immediate and remote. With the improved means of diagnosis which are almost daily being devised the procedure is certain to become more frequent and beneficial. But such operations are only justifiable when undertaken by those who fully realize their difficulties and dangers and who have studied their technique in every detail.

Malignant Disease of the Pelvic Organs.—A. Don notes that malignant disease of the pelvic organs is so common and its operative treatment is yet so varied and on the whole so unsatisfactory that it is highly probable that no finality of method of dealing with the disease has yet been reached. The crux of the whole problem seems to be the disposal of the ureters and the eradication of malignant metastases in the walls of the pelvis.

Congenital Heart Disease.—Sir Dyce Duckworth reports three cases of this condition occurring in one family of marked gouty heredity. While paying little attention to the idea of strong maternal impressions, one may yet suspend judgment respecting the influence sometimes of lesions due to rheumatic, gouty, and syphilitic toxins on the fetal endocardium. The latter are certainly most rarely met with. One should remember that the placenta is permeable by microorganisms and toxins, and further studies in this direction are very desirable.

Variability of Agglutination of Bacillus Typhosus and Micrococcus Melitensis by Normal Sera.—E. C. R. Fox concludes from his investigations that all strains of organisms used for the agglutination reaction should be tested quantitatively as regards agglutinability. The laboratory strain used should be tested against the sera of as large numbers as possible of healthy individuals. The laboratory strain should be tested against the sera of a large numbers of persons known to be suffering from the disease caused by the specific organism, and also of persons suffering from diseases caused by allied organisms, before differentiation between the diseases can be attempted by means of the agglutination test.

Influence of Malta Fever on the Fetus.—R. Samut reports a case in which the fetus had been exposed *in utero* for 21 days to the influence of those abnormal conditions of the maternal blood consequent upon a severe attack of Mediterranean fever. The child's blood and cerebrospinal fluid yielded a positive reaction to *Micrococcus melitensis* in large dilution. This organism could not be recovered from the internal organs of the fetus. Acute infectious diseases are known to be transmitted by the maternal blood to the fetus *in utero*, endangering or in-

terrupting pregnancy. Thus cases of intrauterine variola are by no means rare, while intermittent fever has been known not only to attack the fetus, but in some instances the attacks have continued after birth, and in all the child had at birth an enlarged spleen. There seems to be no reason, therefore, why Mediterranean fever should not be transmitted from mother to child during gestation. The presence of agglutinins alone in the reported case raises the important question whether, in the absence of the *Micrococcus melitensis* in the fetal organs, they could have been elaborated by the fetal blood, or whether they were transmitted directly from the maternal to the fetal circulation.

Accidents Arising from Color-Blindness.—F. W. Edridge-Green states that a large number of such accidents arising from color blindness in pilots and railway engineers have been reported.

Bilharziosis and Ankylostomiasis in Egypt.—G. W. G. Hughes states that of the recruits to the Egyptian army who are sent to Cairo for medical examination 7.5 per cent. have bilharzia ova in their urine. One of the most striking results of ankylostomiasis in the young is the stunting of growth. The extent of the ravages of ankylostomiasis among the male population of Egypt is indicated by the large number of stunted individuals.

X-Ray Treatment of Sarcoma.—J. Delpratt Harris reports beneficial results following the use of massive doses of the *x*-rays in the treatment of a round-celled sarcoma of the lower jaw in a boy four years of age.

Acute Plastic Iritis.—A. A. Bradburne reports a case of this condition in which marked improvement followed the use of antistreptococcus serum. The patient had given evidence of general infection, supposedly rheumatic, but blood examination had revealed the presence of the streptococcus. It is supposed that certain antitoxic sera, even if they do not possess specific action, have marked therapeutic properties of liquefying and aiding absorption of the exuded lymphs.

Syphilitic Necrosis of the Cervical Vertebræ.—F. X. J. Callaghan, in reporting a case of this condition, states that syphilitic necrosis may give rise to all the clinical features of tuberculous caries, but the onset in the former is more sudden and the progress more rapid. In most cases valuable information is obtained from the history of the patient, the presence of other evidences of syphilis, and by noting the effect of antisyphilitic treatment.

Portal Pyemia and Hemorrhoids.—D. A. Alexander reports a case in which portal pyemia occurred as an extension from a thrombosis of the hemorrhoidal veins.

Pulmonary Tuberculosis Among Sailors.—By M. MacKinnon. (See page 791.)

A New Thermotherapeutic Method in Gynecology.—By S. Flatau. (See Medical Record, October 7, page 715.)

Myeloid Leucemia with Chylous Ascites.—H. S. Furness and G. F. Stebbing report a case of this condition occurring in a male aged 40 years. The interest of the case lay in the presence of large numbers of myelocytes in the ascitic fluid and urine, the chylous nature of the ascites, and the extensive general enlargement of the lymphatic glands.

Some points in the Treatment of Severe Talipes. R. P. Rowlands.
A Case of Wry-Neck Following Infantile Paralysis: Treatment: Result. F. Hernaman-Johnson.
A Record of Four Hundred Cases of General Anesthesia Preceded by Scopolamine. F. Rood.
The Brighton United Twins. J. A. Rooth.
The Treatment of Syphilis by Salvarsan. C. H. Browning and I. McKenzie.
Salvarsan in Leprosy. F. A. and F. L. de Verteuil.

Treatment of Severe Talipes.—R. P. Rowlands believes that the operations for talipes in common use are not radical enough. Too much is expected from tenotomies and similar tinkering measures ,and too much is left to the after-treatment, especially with hospital patients. It should be one's endeavor to anticipate the well-known tendency to recurrence, and to design one's operations accordingly, making the patient as independent as possible of prolonged after-treatment by instruments.

Torticollis Following Infantile Paralysis.—F. Hernaman-Johnson urges that every case of acute infantile palsy should be kept under observatioi for some time with a view to the possibilty of a supervening wry-neck. If the lesions in the cranial nerves concerned have been but slight, the deformity may not manifest itself for many months. The sooner the condition is diagnosed and treated the better are the prospects of cure. In the early stages faradization alone may suffice to check the deflection of the head. It must also be remembered that the tendency of the facial hemiatrophy is to increase from year to year, just as a paralyzed limb fails to keep pace with its fellow in rapidity of growth. Faradic stimulation, if begun sufficiently early, does much to lessen these inequalities of development; the interrupted current should, therefore, always be given a careful and persistent trial.

General Anesthesia Preceded by Scopolamine.—F. Rood precedes general anesthesia with the administration of 1-100 grain of scopolamine, 1-120 grain of atropine sulphate, and 1-6 grain of morphine tartrate. From the point of view of the patient this preliminary treatment either blots out or robs of its terrors the preliminaries of an operation, which in some cases, as, for instance, exopthalmic goiter, is a very real advantage. It also diminishes the discomforts of after-pain, etc, by lengthening the period of unconsciousness; postanesthetic vomiting also is lessened. The freedom from sepsis and salivation obtained by the administration of ether by the open method, in combination with atropine, greatly reduces the tendency to pneumonia. From the point of view of the operator the quiet respiration and relaxation which are usually obtained are of great assistance. Finally, there is the undoubted advantage of being able to substitute with equally good results a safe drug, such as ether, for a dangerous one, such as chloroform.

The Brighton United Twins.—J. A. Rooth describes this case of pygopagi. The twins are girls and are now two and one-half years old. They are joined back to back by a fleshy and cartilaginous union in the sacral region, and have a common anus. Each has a separate vulva and vagina. Either twin may be affected with bronchitis, diarrhea, or constipation, although the other twin may not be at the time similarly affected.

Salvarsan.—C. H. Browning and I. McKenzie recommend as the best possible means of producing a complete sterilization in syphilis a combined therapy. Where there is the suggestion of a primary syphilitic lesion, even if spirochetes cannot be found and the serum reaction is negative, treatment should be begun without delay. An intravenous injection of an alkaline solution of salvarsan should be given (0.4 to 0.5 gram in the case of a man), and this should be repeated in three weeks. After each injection a course of mercurial inunctions should be given.

Salvarsan in Leprosy.—F. A. and F. L. de Verteuil report their results in the treatment of leprosy by means of salvarsan. Though there was little change to be noticed in the outward manifestations of the disease, there were some noteworthy differences in the appearance of microscopic slides taken before and after injection. The preparations were made from scrapings taken beneath the dermis over leprotic nodules. In all the tubercular cases the bacilli were still plentiful; in the anesthetic case, however, there was a noticeable reduction in their number. The chief change, present more or less in all the cases, was in the appearance of the bacilli. They had become gran-

ular, with coccothrix-like distribution, many being clumped together in granular-like masses. In other cases granules in large numbers were to be seen scattered all over the field.

Laceration of the Intervertebral Joint Capsule of the Cervical Vertebræ as a Typical Obstetrical Trauma.—Stoltzenberg in the course of 75 autopsies on newly born infants found this injury present in 9 cases. He considers that this incidence of 12 per cent. warrants him in calling the accident a frequent one. The exact lesions encountered are as follows: laceration of the capsule of the lateral articulation, laceration of the neighboring portion of the intercrural ligament, laceration of the vertebra in one of its cartilaginous strata. The injury becomes dangerous through the resulting hemorrhage into the membranes and intra-membranous canal. It is produced through the operation of deviation from the longitudinal traction upon the spine. This may occur in the after-coming head when this is drawn sidewise as a result of fixation by the trunk or arm and in shoulder presentations.

Causes of Acetonuria in Pregnancy.—Porges and Novak believe they have shown that acetonuria in pregnancy is due to defect of carbohydrates in the diet and that it differs from acetonuria in the nongravid only in the fact that carbohydrate intolerance is reduced to a lower level. If we recall other anomalies of metabolism in pregnancy we perceive a key to a solution of the problem of the relation between lack of carbohydrates in the diet and carbohydrate intolerance. To these metabolic disturbances belong the lowering of the limits of assimilation in the gravid as well as the increase of oxyproteinic acids and polypeptides in the urine of the same. These disturbances are due probably to a depression of the hepatic functions which is revealed by demonstrable changes in the circulation, lack of glycogen, and fatty infiltration. In the author's material an insufficient metabolism of fat no doubt existed. The acetone bodies represent an intermediate stage in the transformation of fat to carbohydrates. Acetonuria in the gravid is therefore one more evidence of a depressed hepatic function.

Treatment of Pneumonia.—Schiele believes that skill in treating pneumonia is founded on the intelligent use of a few simple and time-honored remedies and procedures. We should know when, where, and how to employ these. We should distinguish between the mechanical death and the toxic death. During the 24 hours following the crisis cardiac stimulants should be used continuously. If post-critical delirium sets in morphine and camphor should be used. Opiates are not contraindicated if painful respiration is present, for by relieving pain they enable the patient to breathe more deeply. The physician should favor the patient's mental state by psychical methods and by securing him sleep and having him made comfortable in every way. A good easily potable white wine also assists the mental state and aids nutrition. If the patient is pulseless digitalis is indicated. Venesection may avert fatal edema of the lungs.

September 19, 1911.

Laparothoracoscopy.—Jacobaeus gives an account of his new diagnostic resource, which is not wholly original with him since Kelling has described a similar method of "celoscopy." The author has used a Nitze's cystoscope, No. 12, on 115 subjects. He performed laparoscopy 80 times on 45 patients, chiefly with hepatic diseases, tuberculous peritonitis, and abdominal cancer. Thoracoscopy was done 35 times on 27 subjects for the various affections of the pleural cavity. Thoracoscopy seems to give the greater promise. The patients receive local anesthesia and the cystoscope—a small affair—is introduced directly into the pleural or peritoneal cavity through a sufficient opening. The technique does not accompany the present article.

Biological Treatment of Peritonitis.—Kuhn claims that the rational treatment of peritonitis consists in the direct irrigation with solutions of sugar. The latter, as shown by studies in culture media, tends to antagonize the formation of proteolytic enzymes and toxins and to assist in the genesis of antibodies. It also antagonizes the formation of fibrin. This treatment has been tested with good results in experimental pathology. Glucose is used in 5 to 10 per cent. solution after operations, and in conjunction with saline irrigation.

Heredity in Tuberculosis.—Reiche cites many statistics, of which the following is an example: Of nearly 8,000 cases of the disease, 85 per cent. showed no inheritance while in 15 per cent. the latter was in evidence. A larger percentage of women were affected by heredity. Paternal transmission was considerably more in evidence than was maternal transmission, while crossed or double inheritance was present in about 10 per cent. of all hereditary cases. The course of phthisis does not appear to be modified by inheritance. The application of the so-called numerical method shows that this plays but a subordinate rôle.

Retention of Placenta from Premature Use of Ergot.—Schmid relates a case of this sort and cites a few others from literature. Such experiences are exceptional, for ergotin has been injected in hundreds of cases with impunity. The tetanoid contraction of the uterus after expulsion of the fetus and following the use of ergot shows plainly that the drug is at fault. Pituitrin will no doubt soon displace ergot in obstetrics, for its action is much more constant and less violent. It is efficient in postpartum hemorrhage, yet could hardly cause retention of placenta.

September 21, 1911.

Excess of Male Births.—Jendrassik sums up a consideration of this subject as follows: The sex of a child is determined by heredity. From four to five generations have an influence on the individual. Following Mendel's law a like number of boys and girls are born, but over and above these are 4 per cent. of nominal males who, however, possess feminine qualities. This explains the excess of male births. From another point of view boys die in greater numbers up to the fourth month from congenital weakness. Individual qualities of descendants come from their progenitors. Only those qualities derived from five generations are stable in pure propagation; besides it is not possible to influence much the quality of the child, for improvement and decline succeed each other alternately.

Genealogy and Inheritance from the Psychiatric Standpoint.—Sommer divides the material into four groups: 1. Inheritance of normal qualities, morphological, physiological, and psychological. 2. Inheritance of pathological qualities—corporeal, spiritual—and congenital, late appearing, and periodical. 3. Inheritance of qualities injurious to society—corporeal, spiritual. 4. Origin of the qualities which form genius through certain crossings.

Quinine in Urticaria.—Wolff relates a severe case of urticaria in which he obtained good results from quinine. He recalls that the same drug has given similar results in pemphigus. This action of quinine, especially in children, is so striking that it must possess great significance, yet the number of cases is too small to enable us to explain it. Most cases of urticaria are now accounted for by anaphylaxis; and it has been recently shown that *in vitro* quinine is able to disintoxicate anaphylatoxins. This of course suggests a much more extensive use of quinine, for example in serum disease.

Insurance Medicine.

Association of Life Insurance Medical Directors.—At the twenty-second annual meeting of this association, held in New York City on October 4 and 5, the following officers were elected: *President*, Dr. Brandreth Symonds of New York; *First Vice-President*, Dr. Harry Toulmin of Philadelphia; *Second Vice-President*, Dr. Edward K. Root of Hartford, Conn.; *Secretary*, Dr. William Evelyn Porter of New York; *Treasurer*, Dr. A. S. Knight of Rochester, N. Y. *Executive Committee*, Drs. F. C. Wells, E. W. Dwight, and Robert L. Burrage.

Alcohol and Life Insurance.—Whitfield Harral says that the question of the use of alcohol is a most important one in considering an application for insurance. When used daily alcohol handicaps the individual in the performance of his duties and renders him an easier victim to disease. Its prolonged use results in fatty degeneration or in fibrosis. Catarrhal conditions of the respiratory tract are produced by the alcohol eliminated through the lungs. It attacks the stomach, the liver, and the kidneys, and interferes with metabolism. Until recently insurance companies regarded "Ansties' limit" as the maximum amount of alcohol that could be taken without harm, namely, a daily allowance of one and one-half ounces of absolute alcohol, or three ounces of ardent spirits, two wineglassfuls of sherry, or other strong wine, three tumblerfuls of strong ale or porter, five tumblerfuls of light ale or beer. This amount has proved to be too great, and the limit now considered physiologically permissible is from two-thirds to three-quarters of an ounce of absolute alcohol, or its equivalent, in one-half pint of champagne, one and one-half ounces of whiskey, or two to three glasses of beer. Individuals who have taken the Keeley cure should be refused insurance in most cases. More favorable applicants should be issued endowment policies terminating at the age of fifty, and then only provided it has been five years since the cure was taken, and the applicant has been a total abstainer in the meantime.

Nelson's table shows the influence of alcohol upon life expectancy at various ages:

Age.	Intemperate.	General.
20	15.5	44.2
30	13.8	36.5
40	11.6	28.8
50	10.8	21.2
60	8.9	14.3

—*Proceedings of the Medical Section, American Life Convention, New Orleans*, February, 1911.

Suicide.—The great majority of suicides are not persons physically ill, but individuals in good health and capable of "making a living." The reasons for suicide have been much discussed. Economists have decided that suicides in most cases depend not upon the individual wills, but upon certain external factors, such as the season of the year, the economic status, and the age of the individual. Psychiaters have been led to consider all suicides as insane persons. The latter view has lately found much opposition. Von Oettingen sees in suicide a degeneration of the will, making an individual a slave of some temporary circumstances or of his own passions. He thinks that not more than one-third of suicides are insane individuals. Masaryk shows that many individuals who intended suicide and were prevented from carrying it out have proved to be mentally normal in later life. Brasch thinks that most suicides are persons afflicted with mental or physical disease of some nature; he quotes many autopsies in proof of this. Gaupp and Stelzner have lately carefully examined all individuals sent to their clinics after unsuccessful attempts at suicide. In two hundred females Stelzner found sixty-five cases of melancholia, thirty-two cases of psychopathic constitution, thirty-one cases without any manifest psychic disturbances, twenty-four cases of acute paranoia, and eleven cases of epilepsy. These figures show that normal individuals are rare among attempted suicides, and Gaupp's work confirms this conclusion. The great majority of suicides, however, are not frankly insane but persons of psychopathic constitution. Hübner has found that illegitimate pregnancies, suicides, and crimes against persons rise gradually in frequency in the spring and diminish toward the end of summer. The highest incidence occurs in the months of June and July. Both suicides and depressive insanities increase in incidence with increase in age. They also show a rise in incidence at puberty and the first years of sexual maturity.—*Blätter für Vertrauensärzteder Lebensversicherung*, May and June, 1911.

Selection of Risks from the Actuarial Standpoint.—Arthur Hunter points out that little has been written on the selection of risks from the actuarial standpoint, nor on the manner in which the actuary may assist the medical director in the medical selection. It is likewise pointed out that the need for such information is great at the present time, in view of the large number of young actuaries who have become connected with recently organized companies in which the medical directors have had little or no experience in the selection of risks. The medical directors are usually physicians who have been examiners in life insurance companies and whose work has been largely confined to giving a description of the physical condition of the applicant and not to determining whether he should be accepted for insurance. The young actuary has seldom had practical experience in the phase of the work on which the medical director calls the actuary into conference and the object of this paper is to assist these young men on a point on which little reliable information has been published. The medical director nowadays should have a knowledge of mortality statistics and the actuary should learn the views of the medical director in order to properly compile statistics bearing on the selection of risks. The actuarial society and the medical directors' association have combined to carry on a mortality investigation, but before this combined action in many individual offices the medical and actuarial departments had been working in harmony for several years.

With the exception of a very few companies which accept under-average lives the usual custom of treating applicants for insurance is (1) to accept standard risks, (2) to reject substandard risks, and (3) to grant endowment policies or other high priced plans to borderline cases. Because there must be in the minds of the medical directors a standard by which the cases are judged, the word "standard" is used by Hunter to denote cases accepted on the plan applied for. Of the total business received by the companies probably four-fifths comes within this standard. Another class of cases exists in which there is some slight defect but in which there are so many favorable features that comparatively little expert knowledge is required to handle these cases properly. Between these types and the kind which should undoubtedly be declined, are the slightly unfavorable, the border line and the somewhat doubtful cases, regarding which there is considerable difficulty and great diversity of practice among the companies. It is with regard to the debatable cases that the actuary is frequently invited to cooperate with the medical director and considerable difficulty arises in companies which have no available statistics. In dealing with such types the actuary should bear in mind that the disposition is to consider each case as one of a group; whereas the medical director having been trained as a physician, is disposed to treat each case as an individual. As a matter of fact the actuary should learn to look upon each case as one of a type, but modified to the extent to which it departs from the average. The judgment of

the medical director is displayed in making the application of the variations within the type to the individual risk.

The sources of information regarding mortality at the disposal of the medical director in determining the value of each risk are several; perhaps the most of these are statistics covering the groups of lives. In this relation the actuary should be of especial assistance to the medical department, and should have a knowledge of all statistics bearing on mortality among insured lives and also a knowledge of the various factors which enter into the determination of the value of risks. However, in the selection of risks the great difficulty arises with the borderline cases and with the best of those that come within the unfavorable group. It is in the treatment of the borderline cases that the numerical system is of great assistance in determining the value of the risk because it is in cases of this type that the judgment of the medical director is apt to vary.

As the actuary is frequently brought into consultation in the handling of borderline and unfavorable cases, it is a matter for consideration what the function of the actuary should be. His first duty is to prepare for the guidance of the medical department tables showing the mortalities to be expected under the various favorable and unfavorable factors. The main source of such information is the specialized investigation, soon to be superseded by the medico-actuarial investigation. Unless a company has prepared its own mortality tables by classes other sources of information regarding the gravity of the various physical impairments are few. There are several interesting papers in the "Transactions of the Medical Directors' Association." As to statistics on occupation, there is a good source of information in addition to the specialized variety in Dr. Tatham's Report to the Registrar-General of England, published in 1907. Having prepared a table of the unfavorable features the question arises of making allowance for the favorable features existing in given cases alongside of the unfavorable. No rules can be laid down for the guidance of a young actuary in such matters, as the policy of the management must largely determine the course to be pursued. The question of moral hazard is dealt with at length and throughout the paper excellent tables illustrating points are given, but which can only be referred to here. In conclusion the writer regrets that he has been able to give but little information regarding the mathematical basis for determining the value of risks, but that cannot be remedied as published data are not available. With the publication of the results of the medico-actuarial investigations a large collection of reliable statistics will be in the hands of the actuaries for application to the methods discussed in the paper.—*The Transactions of the Actuarial Society of America,* May 18 and 19, 1911.

The Prevalence of Pulmonary Tuberculosis Among Sailors.—M. MacKinnon states that not only is tuberculosis a very prevalent disease among sailors, but also cardiovascular diseases and their effects are extremely common. The latter, however, are rightly attributed more to hard work, alcohol, and syphilis—a trio still closely connected with the sailor—than to inefficient accommodation and ventilation. It might be expected that the sailor who presumably commenced his seafaring life in good health would maintain perfect health, and of all people would be the least liable to contract tuberculosis. In the merchant service such is not the case. The prevalence of the disease is marked and the suffering produced enormous. No better proof could be required of the infectious nature of pulmonary tuberculosis than that supplied by the frequency of that disease among sailors, the vast majority of whom have no hereditary tendencies to that disease, but, on the contrary, are physically of such build and good development as to preclude any suspicion of that taint. When, however, a single member of a crew suffers from tuberculosis he becomes a grave danger to all the others. Firemen, engineers, greasers, cooks, and stewards pass most of their time below deck in stuffy atmospheres, in ill-ventilated, dark, and dusty rooms, with the too frequent result that in the course of time anemia is produced, health deteriorates, and they become a ready prey to the tubercle bacillus. Additional factors, such as the abuse of alcohol, venereal diseases, irregularities in diet and sleep, are all causes that increase the susceptibility to pulmonary tuberculosis. The author presents the statistics of the Dreadnought Hospital which show that the percentage death-rate from phthisis in this institution varied from 31.2 in 1890 to 27.2 in 1900. In comparing the cases of tuberculosis admitted to the hospital during the past twenty years, it is noted that the greatest number of admissions occur among the able-bodied seamen, among whom are included for convenience quartermasters, boatswains, ship's carpenters, and others who work on deck but are not classified under any of the other headings. The high admission-rate among the "able-bodied" may partly be accounted for by the fact that there are more sailors included in this than under any other heading, and it frequently happens that seamen of foreign nationality, unable to talk English, are admitted as sailors under this category. Next come the firemen, and although the admissions among them are much less than in the preceding class, there is a very much greater incidence of phthisis among them than in any of the other succeeding classes—about equal, indeed, to the total of all the other sections put together. Stewards supply a greater percentage than cooks. Under the officer class are included first, second, and third mates and the captains. The rate among them is very small. Tuberculosis is more frequent among those who spend most of their time below deck than among those who work for the most part on deck. In the navy tuberculosis has decreased during the past ten years. This is no doubt due to the fact that the conditions under which the sailor lives as regards sanitation and accommodation have vastly improved, and when cases of tuberculosis occur they are immediately invalided out of the service. In the merchant service there is still much room for improvement. Not only is there need of this in accommodation and ventilation, but the elementary principles of hygiene should, as far as possible, be instilled into the sailor and the danger of indiscriminate spitting brought before his notice by printed forms or otherwise. More stringent precautions also should be taken in that all subjects of tuberculosis should be discharged from the service, and no man who, on medical examination, shows signs of tuberculosis or gives a history of having suffered from it should be engaged for service on board ship.—*Lancet,* September 23, 1911.

May Syphilis Be Considered an Industrial Accident?—The *Journal of the American Medical Association* states that the Paris courts have been called on to decide whether syphilis contracted in the exercise of his profession by a mechanician-dentist constitutes an industrial accident. A mechanician-dentist working for a surgeon-dentist was wounded in the little finger; the patient being syphilitic, the mechanician contracted syphilis. On the ground that his infirmity was permanent and that he had experienced a reduction of 80 per cent. in his professional practice, the mechanician-dentist demanded from his employer an annual income of 2,912 francs. The courts did not accept his point of view on the ground that the profession of dentist was a liberal profession and that the dentist employer was not subject to the law with regard to industrial accidents. In the liberal professions, syphilis cannot, therefore, constitute an industrial accident.

Improved Risks.—The death rates recorded by the leading insurance companies during 1910 were extremely low as compared with the "expected" death rates embodied in the standard mortality tables. The *Spectator* publishes a list of fifty companies which "show an average saving on mortality of over 25 per cent., while fifteen exceeded 30 per cent. and, of these, four showed savings of over 40 per cent."

Book Reviews.

Notes on Dental Metallurgy. For the Use of Dental Students and Practitioners. By W. Bruce Hepburn, L.D.S. (Glasgow); Lecturer on Dental Metallurgy and Visiting Dental Surgeon in the Glasgow (Incorporated) Dental Hospital and School. Price $2.00. New York: William Wood & Co., 1911.

This is an excellent little manual presenting in condensed form the essentials of metallurgy, and meeting in this respect the requirements of various schools and colleges of dentistry. Modern processes of extraction of metals, and modern theories regarding the composition and behavior of amalgams are described. There are chapters on pyrometry, casting of metals, testing of amalgams for their physical properties, and there is one chapter dealing with the behavior of metals in the mouth, a subject of eminent importance in applied metallurgy. The dental practitioner will find many useful tables in the appendix of this book: tables of alloys, of physical constants of the more important metals, tables of thermal and electrical conductivity, of thermometric scales, etc. The book may be recommended to the dental student as a clear and succinct presentation of a most practical subject, bearing the seal of the author's mature experience.

Alcohol, A Dangerous and Unnecessary Medicine. How and Why. What Medical Writers Say. By Mrs. Martha M. Allen, Superintendent of the Department of Medical Temperance for the National Woman's Christian Temperance Union. Marcellus, New York: Department of Medical Temperance of the National Women's Christian Temperance Union, 1911.

It is true that nowadays alcohol is not being used as freely medicinally as it has been in the past, and that many well-known authorities in the profession actually condemn its use, both in health and disease. It is unlikely that physicians looking for new light on this subject will be willing to find guidance in Mrs. Allen's book. It is written from the viewpoint of the partisan, and for this reason its scientific value is *nil*. A sample of its logic appears in the preface: "The use of antitoxin in diphtheria has driven out whiskey treatment in that disease with markedly favorable results. Under the whiskey treatment death rates ran up to 55 and 60 per cent.; now the diphtheria death rate is very low." It is unnecessary to add further comment.

Spirochætes. By W. Cecil Bosanquet, M.D., Fellow of the Royal College of Physicians, London. Price, $2.50 net. Philadelphia and London: W. B. Saunders Company, 1911.

This volume appears at a time when the general interest in spirochætes is rapidly growing, and it contains practically all the information which the average man desires or needs. In the first part the author has compared the statements of different writers on the morphology and behavior of these organisms and has endeavored to establish their characteristic features. As a result of this study and of his own work he is inclined to place them nearer to the bacteria than to the protozoa. The second part consists in brief descriptions of some fifty or more species and of the methods employed for examining them. For the investigator who wishes to pursue the subject further there is appended a bibliography including all the more important papers on the subject. Throughout the book the description is supplemented by drawings. The book is artistically bound.

Public Hygiene. By Thomas S. Blair, M.D., Neurologist, Harrisburg, Pa., Hospital; Author of "A Practitioner's Handbook of Materia Medica," "A Practitioner's Handbook of Modern Medical Treatment," etc. Assisted by Numerous Contributors. In Two Volumes. With 158 Illustrations. Price $10.00. Boston: Richard G. Badger, The Gorham Press, 1911.

This work is unique both in its scope and in the method of handling the subject matter. It treats of hygiene not so much from the viewpoint of the individual, but, as its title indicates, from the viewpoint of the public. Necessarily, the welfare of the individual is at once a prerequisite to, and a result of, the welfare of the community as a whole. Many of the subjects included in these volumes have not yet found their way into the treatises on hygiene. A list of the chapter headings will indicate the comprehensive nature of the plan of this work and the newness of many of the topics treated. Volume 1 consists of chapters on the following: The family versus the community; hotels, lodging houses, and public buildings; school inspection and college sanitation; penal institutions and hospitals for the insane; maternities; places of amusement and of dissipation; slums and town nuisances; special rural hygiene and sanitation; State Departments and Boards of Health; a proposed Federal Bureau of Health; local Boards of Health and sanitary officers; army and navy sanitation, or hygiene of camps; the coroner and the physician; quarantine, and infectious diseases. Volume 2 comprises chapters on the following: Immunity; epidemics; disinfection; tuberculosis sanatoria and dispensaries; home hygiene and interior sanitary installations; pure drugs and foods; public works and corporations; public carriers and sanitation; laboratory methods in sanitation; medical societies and sanitation, and an appendix on infectious diseases of animals, sanitary construction and hygiene of the mails. The author has availed himself of the assistance of numerous contributors and collaborators, and has drawn freely from many recent official reports, volumes, and periodical publications, in the preparation of this work. The project that he has attempted is one that would require for its complete presentation a work of encyclopedic magnitude. For this reason these two volumes, with their total of 644 pages, cannot give more than a fragment of the vast material available. This work, therefore, cannot be regarded as a scientific treatise; it is besides somewhat discursive and disconnected. Nevertheless it is very readable and interesting, and in some of its chapters it is highly illuminating. One of these is the chapter dealing with the State Departments and Boards of Health, and giving an outline of their legal status and activities in all of the States and Territories of the Union. The chapters on school inspection and college sanitation, on penal institutions, and hospitals for the insane, on places of amusement, and slums, are replete with valuable information and, with other equally important portions of the work, indicate that the writers are alive to the most modern developments in sanitation. The detailed exposition of the pure food and drug laws, the elaborate description of the sanitary aspects of public works and corporations, and of public carriers, combine with the features already mentioned to make this work one that the sanitarian must add to his reference library. The general practitioner and even the lay reader will find in its pages a great deal of interesting and instructive material. There are numerous excellent plates, and the paper, typography, and binding are considerably superior to those found in the average medical textbook.

What to Eat and Why. By G. Carroll Smith, M.D. Price $2.50. Philadelphia and London: W. B. Saunders Company, 1911.

The author does not attempt to cover the whole subject of dietetics in this book. Very little is said about the chemistry of foods, and the dietary treatment of only the most important diseases has been discussed. In considering the individual diseases, Dr. Smith gives reasons for the necessary changes in diet, rightly assuming that if these principles are once thoroughly grasped, dietetic therapy becomes simplified and the physician will be able to intelligently prescribe a diet for any disease. A few diet lists have been given, comprehensive and varied enough to cover the different phases of the same disease and to modify the monotony of the diet. The book will certainly be appreciated by the profession.

A Manual of the Diseases of Infants and Children. By John Ruhräh, M.D., Professor of Diseases of Children in the College of Physicians and Surgeons, Baltimore. Illustrated. Third Edition, thoroughly revised. Price $2.50. Philadelphia and London: W. B. Saunders Company, 1911.

Within the limits of a manual the author has succeeded in crowding a great deal more than is included in many textbooks of larger size. Brevity is the crowning feature that permits the inclusion of descriptions of rare conditions as well as of the common ones. Among the former one notes adolescent rachitis, chronic family jaundice, speech defects, multiple exostoses, etc. The chapter on infant feeding is particularly thorough in its presentation of the numerous methods and working formulæ, while that on therapeutics, with its detailed description of the best modes of administering drugs to children, and that on the medical inspection of school children, are particularly deserving of mention. Errors are inevitable in a book of this kind; cleidocranial "dystosis" should be dysostosis; achondroplasia is not fetal rickets, nor is it fetal myxedema. These, however, are of minor importance. The numerous illustrations and the footnote references to the literature are valuable features of this uncommonly useful little book.

MENINGITIS, SINUS THROMBOSIS, AND ABSCESS OF THE BRAIN. With Appendices on Lumbar Puncture and Its Uses and Diseases of the Nasal Accessory Sinuses. By JOHN WYLLIE, M.D., author of "Tumors of the Cerebellum." Price $3.00. New York: Paul Hoeber, 1911.

THIS is a small volume of 258 pages, devoted to a consideration of diseases which in their earlier stages are frequently difficult to differentiate from one another. The general practitioners, no less than the aural and the general surgeon, will find in this book a careful discussion of the diagnostic difficulties which frequently present themselves. On some topics the author treads on unfirm ground, as when he says, in giving the treatment of forms of acute suppurative or idiopathic meningitis other than those secondary to otitis: "The most scientific treatment would be the withdrawal of 15 to 20 c.c. of cerebrospinal fluid, from which a serum should be prepared and reinjected into the spinal subarachnoid space with as little delay as possible. Does the author mean that a vaccine should be prepared? If not, he can hardly expect that a specific serum can be prepared, at any rate, at the present stage of progress in serum therapy. In spite of this vagueness the book is a most interesting and suggestive one.

FIRST AID IN NURSERY AILMENTS. By EMELYN LINCOLN COOLIDGE, M.D., author of "The Mothers' Manual," and Editor of the Babies' Department of the Ladies' Home Journal; Physician in Charge of the Babies' Class of the Society of the Lying-In Hospital of New York City. Price 50 cents. New York: Sturgis & Watson Company, 1911.

THERE is a constant demand for books of this nature by young and inexperienced matrons, who find it impossible or inconvenient to consult their physician in the little but nevertheless important emergencies that arise in the nursery. This book is a safe guide; it makes no attempt to take the place of the physician, and by its mention of simple and in some instances popular remedies it is adopted for use by mothers who are traveling or who live at a great distance from medical aid.

KLINIK FÜR PSYCHISCHE UND NERVÖSE KRANKHEITEN. Herausgegeben von ROBERT SOMMER, Dr. MED. ET PHIL., o. Professor an der Universität Giessen. VI Band. 1. Heft. Preis, M. 2.00 Halle a S.: Carl Marhold, 1911.

THIS number of the Clinic of Psychic and Nervous Diseases contains the following articles: I. The distinguishing between epileptic and catatonic states; particularly by means of associations; by G. Klepper. II. The investigation of associations in maniacs; by K. Kilian. III. The more exact investigation of the most diverse motor phenomena, particularly voluntary movements, by means of graphic methods; by F. Pfahl.

THE PRACTICAL MEDICINE SERIES, Volume III. THE EYE, EAR, NOSE AND THROAT. Edited by CASEY A. WOOD, C.M., M.D., D.C.L. ALBERT H. ANDREWS, M.D., and GUSTAVUS P. HEAD, M.D. Series 1911. Price $1.50. Chicago: The Year Book, Publishers, 180 N. Dearborn Street.

THE diseases of the eye, ear, nose and throat receive about equal consideration in this volume. The literature of the past year has been thoroughly reviewed and abstracts from the most important articles have been included. In several cases the value of these excerpts is enhanced by the editorial comment which accompanies them. It is sufficient to say that the book maintains the usual standard.

THE NERVOUS LIFE. By G. E. PARTRIDGE, Ph.D., formerly Lecturer in Clark University. Author of "An Outline of Individual Study." Price $1.00 net. New York: Sturgis & Walton Company, 1911.

VOLUMINOUS as is the material on hygiene in all its branches in recent years, nevertheless so practical a book as "The Nervous Life" must claim a niche heretofore unfilled. Here are considered the causes of nervous disorders and the wisest means of controlling them. The author is definitely opposed to "narrow health fads, hobbies, or systems" as a remedy for the shortcomings of modern existence. In the term nervous life he includes two conditions: "First, the nervous social and industrial life, best typified by the stress and strife of our great cities; second, the nervous life as expressed in the temperament of the nervous individual." The range of subjects is wide, embracing self-knowledge, some biological laws, principles of control, the optimum life, food, the skin, exercise, sleep and rest, work, recreation, and suggestion and mental healing. The object of the work is not the discussion of nervous disorders, for the writer addresses himself rather to the well than to the sick. But "the principles of living are not different for well and ill." The book is full of helpful suggestions for the routine of daily living, and is built upon a firm foundation of common sense.

BURDETT'S HOSPITALS AND CHARITIES, 1911. Being the Year Book of Philanthropy and the Hospital Annual. Containing a Review of the Position and Requirements, and Chapters on the Management, Revenue, and cost of the Charities. An Exhaustive Record of Hospital Work for the Year. It Will Also Be Found to Be the Most Useful and Reliable Guide to British, American, and Colonial Hospitals and Asylums, Medical Schools and Colleges, Nursing and Convalescent Institutions, Consumption Sanatoria, Religious and Benevolent Institutions, and Dispensaries. By Sir HENRY BURDETT, K.C.B., K.C.V.O., Author of "Hospitals and Asylums of the World," "Hospitals and the State," "Pay Hospitals of the World," "Cottage Hospitals: General, Fever, and Convalescent," "Burdett's Official Nursing Directory," "The Nursing Profession," "Helps in Sickness and to Health," "The Relative Mortality of Large and Small Hospitals," and Editor of "The Hospital." Price 10s. 6d. London: The Scientific Press, Limited.

IN the issue of this invaluable handbook for 1911 the features which have made the previous issues so acceptable have been retained and some new ones added. The names of the architects of all hospitals, where known, are given, and in the index the popular names often given to public or private hospitals as well as the official names are inserted, thus greatly facilitating reference in case the full title of the institution is not remembered. Much of the text, treating of conditions in the United Kingdom, is not applicable to this country, but the chapters on the volume of charity and on nursing will prove interesting to readers everywhere.

INDEX-CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, United States Army. Authors and subjects. Second Series. Vol. XV. Skin-grafting. Washington: Government Printing Office, 1910.

IN this volume there are 8,804 authors; titles embracing 4,688 volumes and 7,460 pamphlets; and 3,616 book titles and 28,328 titles of journal articles. The value of the work to libraries and to students of medical literature cannot be calculated. In the note of transmissal to the Surgeon-General the editor, Lieutenant-Colonel W. D. McGraw, states that there now are in the Library of the Surgeon-General's office 172,270 bound volumes and 304,708 pamphlets.

MANUEL DE CULTURE PHYSIQUE. Par C. C. PAGÉS, Docteur en médecine, Docteur ès sciences, Vétérinaire délégué de Paris et de la Seine. "Ne cesse pas de modeler ta statue." Eighty-six figures dans le texte. Price 3 fr. 50. Paris: Vigot Frères, 1911.

THE present concise little volume bears the stamp of originality shown in the previous work of this author, who considers physical culture the chief of the arts. The greater part of the text is specially devoted to the needs of men. Two chapters, however, consider physical culture for women. The writer favors exercise in the home rather than in the gymnasium. Health is his chief consideration, and the principal aim of the exercises recommended is the strengthening of the viscera. Simplicity and gentleness of effort are the keynotes of the work described. Consequently the apparatus preferred is arranged with elastic parts so that effort may be graded. A variety of exercises for different times and places are clearly described and illustrated. Exercise out of doors, exercise in the room, exercise adapted for different purposes, and for the different systems of the body, and exercise adapted to different ages. The volume contains 86 illustrations, and will prove a very useful handbook for individuals of all classes.

DIE PRAKTISCHE BEDEUNTUNG DES SALVARSAN (DIHYDRODIAMIDOARSENOBENZOL FÜR DIE SYPHILISTHERAPIE. Von Dr. S. JESSNER, Sanitätsrat. Price 1.80 M. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1911.

THIS brochure of 73 pages presents the subject of the practical significance of salvarsan in the therapy of syphilis from the viewpoint of the experienced dermatologist. The various phases of the subject are discussed: mode of preparation, administration, indications, etc. The author strikes the keynote of chemotherapy when he states that Ehrlich's investigation shows that future studies may enable one to mask or eliminate the toxic properties of a drug and at the same time increase its curative property.

Society Reports.

THE AMERICAN GYNECOLOGICAL SOCIETY.

Thirty-Sixth Annual Meeting, Held at Atlantic City, N. J., May 23, 24, and 25, 1911.

THE PRESIDENT, DR. REUBEN PETERSON, ANN ARBOR, MICH., IN THE CHAIR.

AN address of welcome was delivered by Dr. WALT P. CONWAY of Atlantic City, which was responded to by Dr. PHILANDER A. HARRIS.

The Treatment of Placenta Previa at the Sloane Hospital for Women.—Dr. EDWIN B. CRAGIN of New York said that cases of placenta previa occurring in 25,000 consecutive deliveries were presented for discussion of treatment and were divided into two groups, namely: Series A, those occurring in the first 20,000 deliveries; and Series B, those occurring in the last 5,000 deliveries. In Series A the cases of placenta previa were treated by different methods: by Braxton-Hicks' version and using the half breech as a uterine tampon, or by tamponade of the cervical canal and vagina, or by dilatation of the cervical canal by the Voorhees bags. In Series B the methods of treatment in cases needing any treatment save that of a normal delivery could well be summarized as follows: 1. Dilatation of the cervix and control of the hemorrhage with the largest Voorhees bag which could be introduced, *i.e.* No. 3 or 4. 2. After the largest bag had passed the cervix and good dilatation was obtained, either a version was done and the child delivered by the breech, or if the placenta previa was lateral, or in some cases even marginal, with slight hemorrhage, and the vertex was presenting, the membranes were ruptured and the head was allowed to come down and exert pressure on the lower uterine segment and the edge of the placenta, the delivery being expedited by the forceps if necessary. This use of the elastic bag was extraovular, the membranes being kept intact until the bag passed the cervix and good dilatation was obtained. The first question of importance in any method of treatment was the maternal mortality. In Series B, treated by the present methods, there were forty-nine cases of placenta previa, fourteen of the complete and thirty-five of the incomplete variety. There were two deaths among those of the complete variety, or 14.2 per cent., and two deaths in the thirty-five in the incomplete variety, or 5.7 per cent. In Series A, treated by different methods, there were thirty-nine cases of complete placenta previa with nine deaths, or 23 per cent., and 135 cases of incomplete placenta previa with eleven deaths, or 8.1 per cent. As regards fetal mortality, in Series B, treated by present methods, the total fetal mortality was 51 per cent., while in Series A it was 60.3 per cent. In Series B 63.1 per cent. of the children viable on the admission of the mother left the hospital alive. Regarding the question of placenta previa being an indication for cesarean section, he could only state that he had never met with a case in which he had considered it indicated. He believed that the indication occasionally arose. He had recently performed it in a case of accidental hemorrhage with long, rigid cervix, with profuse hemorrhage, and believed that similar conditions in a placenta previa might well indicate the same operation. That cesarean section was often indicated in placenta previa he did not believe.

Placenta Previa.—Dr. EDWARD P. DAVIS of Philadelphia for clinical purposes divided placenta previa into partial and complete. Under the latter he included those cases in which the placenta, originally low, had entirely covered the internal os by an additional lobe connected with the greater placental mass by a membranous interval. In partial placenta previa hemorrhage might be controlled by evacuating a portion of the amniotic liquid, stimulating the uterus to contraction, and forcing the fetus down against the placenta. Such treatment was not difficult of execution, provided no essential disproportion existed between mother and child. Where delay in dilatation occurred the introduction of a good-sized bag through the ruptured membranes, disturbing the placenta as little as possible, would greatly expedite delivery and control hemorrhage. The Braxton Hicks' method was available in such cases, and if the operator avoided the mistake of proceeding to immediate delivery it would give good results for the mother at the expense of the child. Of late attention had been drawn to the value of intraovular pressure in placenta previa by inserting, with suitable forceps, a good-sized bag through the membranes or placental substance, and by dilating this bag fully, thus controlling hemorrhage through pressure and hastening delivery. In partial placenta previa treated with or without intraovular pressure by a dilating bag the maternal mortality was not high. From rupturing the membranes in partial placenta previa, Novak collected 163 cases, with no maternal mortality, and a fetal mortality of 15.3 per cent. If the operator proceeded to immediate version and extraction, in 878 cases the maternal mortality rose to 8.8 per cent.; the fetal mortality to 71.8 per cent. In Novak's collection of 2,081 cases, reported by different authors, by the various methods of treatment exclusive of cesarean section, the maternal mortality averaged 8.65 per cent.; the fetal mortality 56.72 per cent. In central placenta previa attention had recently been called to the disadvantage of former treatment by the use of the tampon. In spite of antiseptic precautions, infection was not uncommon in these cases, and as this treatment was often employed in private houses, with deficient aseptic technique, infection must be frequent. The tampon did not perfectly control hemorrhage and was but a temporary expedient to prepare the way for some method of delivery. The high fetal mortality of placenta previa, treated by vaginal methods, and the considerable maternal mortality suggested the possibility of delivery by abdominal section. The advocates of suprasymphyseal section urged its adaptability in these cases, and Pankow reported eight successful cases. Sellheim by extraperitoneal section in eight cases secured the recovery of both mothers and children. Vaginal cesarean section in Doderlein's clinic was performed ten times for placenta previa, with the recovery of all the mothers and the greater part of the children. The author had in three cases of central placenta previa operated as soon as the diagnosis could be made out. The mothers recovered without incident; one normal child at term did well; the second child was a monstrosity; the third child, which was premature, did not long survive. He believed there was a close analogy between ectopic gestation and central placenta previa. In both the cardinal dangers were those of hemorrhage and infection; in both palliative measures were insecure and unsatisfactory; in both operative treatment was the only reliable resource. In the present stage of knowledge no method of treatment compared with abdominal cesarean section in central placenta previa, if the lives of both mother and child were to be considered. The mortality of abdominal cesarean section in uninfected cases was now less than 2 per cent. in a large number of cases, and the fetal mortality in a considerable number was often nothing. It was his belief that a considerable amount of bright vaginal hemorrhage in a pregnant patient was always a dangerous symptom; and that during the latter months of pregnancy, mother and child being previously in good condition, such hemorrhage should be considered as indicating a condition fully as critical as ectopic gestation. Such cases should be immediately seen by a competent obstetrician and a very careful examination made. Under favorable conditions delivery by abdominal cesarean section should greatly improve the chances of both mother and child.

A Brief Analysis of Forty Consecutive Cases of Placenta Previa.—Dr. J. Clifton Edgar of New York said the general line of treatment in these forty cases consisted (1) in controlling the hemorrhage and securing cervical dilatation by means of cervical and vaginal packings; (2) completing the dilatation by means of bimanual cervical dilatation, the Pomeroy hydrostatic bag, or the modified de Ribes bag; (3) completing delivery by version and breech extraction, the forceps, simple breech extraction, or spontaneously; (4) the postpartum packing of the uterus to prevent further bleeding and the use of hypodermoclysis, rectal and venous infusion, or other shock treatment; (5) the induction of labor. Of the forty cases of placenta previa, ten were central, nine partial, twenty-one marginal. Seventeen cases were ambulance or emergency ones. Seventeen cases were first seen at the onset of the bleeding; in twenty-three the hemorrhage had lasted from a few hours to several days. Twenty-three cases only were exclusively treated in the hospital; the remaining seventeen had received various treatments before entering this hospital service. In twenty-nine cases the cervical dilatation was two fingers, or less when first seen. Treatment embraced (1) cervical and vaginal gauze packing in thirty-two cases; (2) de Ribes bags in three cases; Pomeroy bag in seven cases; bimanual dilatation as a primary measure in two; gauze packing in ten cases; and induction of labor in nine cases. The methods of delivery were: (1) Version and breech extraction in twenty cases; (2) forceps in six cases; (3) simple breech extraction in five cases; (4) spontaneous delivery in eight cases, making, with one case undelivered, forty cases; postpartum uterine tamponade in forty cases. The maternal mortality was 7.5 per cent.; the infant mortality was 32.25 per cent. He reached the following conclusions: 1. Cervical and vaginal gauze packing was an efficient means for controlling hemorrhage and securing dilatation in placenta previa. 2. The maternal mortality of 7.5 per cent. and infant mortality of 32.25 per cent. were satisfactory, taking into account the fact that about half of the cases were ambulance or emergency cases. 3. Version and breech extraction had a higher infant mortality than delivery by the forceps, simple breech extraction, and spontaneous expulsion.

The Best and the Worst Methods of Treating Placenta Previa.—Dr. Henry D. Fry of Washington, D. C., said the best and safest method to deliver a woman suffering from placenta previa was purely an obstetric problem and its decision should rest with the obstetrician. Men who had handled these cases according to modern obstetric methods; who were familiar with the dangers incurred; who had learned to overcome the difficulties and dangers and knew the limitations of their art; they, and only they, should decide what method of procedure was best for each individual case. Experience clearly demonstrated that maternal interests were guarded best by evacuation of the uterus as soon as the diagnosis of placenta previa was made. In the methods of treatment suggested by the council for present consideration that classified as "c" was by rapid dilatation, version, and extraction. It was implied, but not stated definitely, that the procedure was accomplished at one sitting and that the dilatation was not only rapid but was carried to a degree to permit podalic version, while extraction of the infant was done by active measures. Rapid dilatation of the cervix had no place in the treatment of placenta previa, whether performed manually, by the Bossi dilator, or by vaginal cesarean section. Version by the podalic method was never advisable unless uterine action had softened and dilated the cervix sufficiently to insert the hand. Slow delivery of the infant should be substituted for extraction. Rapid dilatation was accompanied by severe hemorrhage from placental detachment and from uterine laceration during and after manipulation. After dilatation had been obtained in sufficient degree to allow the insertion of two fingers further continuation of the process was likely to endanger the integrity of the soft parts. In other words, the artificial dilatation sufficient to perform bipolar version was comparatively safe, while that necessary for the insertion of the hand and podalic version was dangerous. After version had been accomplished, the leg, breech, and body of the infant successfully plugged the cervical opening and by pressure against the area of uteroplacental detachment prevented the further loss of blood. Bleeding being absolutely under control, every effort should be made by slow delivery to secure dilatation and thereby prevent laceration of the lower uterine segment. His rule was to discontinue anesthesia after having performed version and to hasten uterine action by directing an assistant to rub the fundus of the uterus, and by encouraging the patient to make use of her auxiliary muscles to supplement the uterine force. In multiparae the average duration of labor under these circumstances was one or one hour and a half. Furthermore, it must be recognized that the danger was not over with the successful termination of labor. The mother had yet to run the gauntlet of postpartum hemorrhage and sepsis. The proper application of the intrauterine tampon of sterile gauze was a most valuable agent in safeguarding the patient from the disastrous consequences of further loss of blood. No substitute could be employed safely to control postpartum bleeding in these cases. The cause of death (the thirty-sixth case) in his own series of thirty-eight cases was due to the imperfect manner of application of the gauze by the hospital intern. Laceration of the lower segment of the uterus was a frequent cause of fatality in placenta previa. The complication favored both hemorrhage and sepsis, and next to hemorrhage as a cause of death in placenta previa was sepsis. The area of placental detachment left a raw absorbing surface low down in the uterine cavity instead of at the normal site near the fundal end. Proximity to the vagina favored infection, while laceration of the parts opened the portal for entrance of pathogenic germs. In placenta previa the precinct immediately adjacent to the internal os must be regarded as sacred ground with the sign *noli me tangere;* therefore the invasion of this part with the gauze tampon or with the rubber bag dilator was dangerous. The least dangerous obstetric interference was that necessary to perform bipolar version. The fingers did not come in contact with the danger zone, but were passed through the internal os and directly within the ovular sac. The leg of the infant was brought down, the pressure was exerted from within the ovular sac outward; the uterus was excited to contract; hemorrhage was controlled, and if delivery was left to uterine action the dilatation was natural. Contrast also the duration of time involved in the employment of bipolar version and in the use of the rubber bag dilator. It was a question of minutes in the former and of hours in the latter. Regarding the indications for abdominal cesarean section in placenta previa, he repeated the conclusions of his previous paper. It was advisable in central placenta previa complicated by an undilated cervical canal. Not only must the cervix be undilated, but the tissue must be hard and unprepared for artificial dilatation. This condition existed only in about 5 per cent. of all cases of placenta previa, and was almost never met with in multiparæ. Contraindications for abdominal cesarean section were, first, excessive loss of blood before the opportunity arose for performing the operation; second, a soft and dilatable cervix; and, third, a partial or marginal placenta previa. Previous attempts to dilate and deliver the case by the natural passages; the use of gauze tampons and rubber bags to control hemorrhage, placed such cases on the undesirable list, and if subjected to surgical skill a Porro operation should be substituted for cesarean section.

The Treatment of Placenta Previa.—Dr. F. S. Newell of Boston said that the statistics of the treatment of complete placenta previa showed in general practice a maternal mortality of approximately 40 per cent. In clinics under the care of expert obstetricians the mortality had been reduced to between 3 and 5 per cent. in the same type of cases. This variation could only mean one thing, that the condition was recognized and treated efficiently by the expert where it was palliated by the general practitioner. The important thing in treatment, therefore, was the early recognition of the condition and the prompt termination of the pregnancy. The method of operative procedure must be chosen to suit the individual case; no rule to suit all cases could be laid down. He believed that in a patient at or near term, when mother and child were both in good condition and if the soft parts did not offer undue resistance to dilatation, the best method of treatment was complete dilatation of he cervix followed by immediate extraction of the child, believing that a slight risk to the mother was warranted for the sake of giving the child a reasonable chance for life. When the mother had bled sufficiently to be in anything but first-rate condition the chances for the child were comparatively poor under any circumstances, particularly if it was markedly premature; therefore the treatment to be adopted should be that which would give the least shock to the mother. This was, in his opinion, a partial dilatation of the cervix, bipolar version followed by slow extraction of the child. This method of treatment of necessity sacrifices the child in the majority of cases, but risks the maternal life less than any other method which could be employed. Cesarean section in the treatment of complete placenta previa should, in his opinion, be reserved for those cases in which the cervix was rigid, as would be seen occasionally in primiparæ or in multiparæ with cicatricial stenosis of the cervix, or cases in whom there was a marked degree of pelvic contraction present. If cesarean section was to be adopted as a routine treatment, he believed that the maternal mortality would be markedly increased over what it was at present in cases under expert care.

Dr. Richard C. Norris of Philadelphia said that there were cases of placenta previa which were best treated by abdominal cesarean section, but he believed also that combined experience taught that the number of cases in which indications might arise to require this operation would always be limited, probably about 5 per cent. of all cases of primiparæ. The ideal conditions for cesarean section were a rigid cervix, a viable child, a mother who was a good surgical risk, and the diagnosis made at an early period.

Dr. J. Whitridge Williams of Baltimore said that in cases requiring nothing more than rupture of the membranes he had used exclusively the Champetier de Ribes balloon, and during this entire period he had no maternal deaths, so he considered the results extremely satisfactory. A dangerous method of treating placenta previa in his experience was by rapid dilatation, either with the fingers or with some intrument. As to abdominal cesarean section, the indications for it were so extremely infrequent that one could do without it, and he had not been able to see the justice of the mode of reasoning of the Germans who had been extremely enthusiastic over it.

Dr. Walter P. Manton of Detroit, Mich., had used all of the methods that had been advocated except cesarean section, and he did not recall having seen a case where he thought this operation would be applicable. In the last 1,989 cases of confinement at the Women's Hospital in Detroit they had nineteen cases of placenta previa, and in only one was the placenta centrally implanted. In his own experience he had never lost a mother with the methods that had been advocated. The infant mortality had been between 50 and 60 per cent., although he had not the exact figures. He had not had great success with the Braxton Hicks' method of bipolar version, but by the use of the de Ribes bag and Voorhees bag his patients had come through safely, although the infant mortality had been high.

Dr. Philander A. Harris of Paterson, N. J., had done practically no obstetrics in the last few years. Occasionally he saw a case, so that he had not advanced much in the treatment of cases of placenta previa, and he had been forced to stop with a maternal mortality of 1 per cent. in less than 60 cases of placenta previa of all kinds. He had invented a metallic instrument for dilating the cervix, but as it was unsatisfactory he returned to the method of dilating the cervix with the hand, and when one of the speakers referred to the disadvantages of manual dilatation he wondered whether he was not really wrong as to definition. A hand which was dilating a cervix of certain size could easily tear it, and he wondered whether the gentleman who objected to these methods, which in his hands had been satisfactory, had not torn the uterus over and over again, instead of taking the matter in deliberate fashion and dilating the cervix. He said this in behalf of a method which he thought had been dangerously used. The knife was a useful thing, but he had seen it do harm.

Dr. William S. Stone of New York mentionel a case of accidental hemmorhage in which he decided to do the vaginal operation after the patient was on the table, as the conditions were such that it was the easiest and quickest way to remove the contents of the uterus, and it proved to be such. He had never done vaginal cesarean section for true placenta previa.

Dr. J. M. Munro Kerr of Glasgow, Scotland, said that in the treatment of placenta previa we must distinguish between domestic and hospital practice, and he was perfectly convinced that in domestic practice we could do no better than follow the advice of Dr. Fry, namely, to do version by the Braxton Hicks' method. That was the problem for the general practitioner. In the Glasgow Maternity Hospital they had tried chiefly two treatments: bipolar version and the treatment by bags, and so far their results had differed very little by the use of the two methods. They had, if anything, a little lower fetal mortality, and, if anything, a slightly lower maternal mortality, but it had been very slight indeed, and consequently he could understand very clearly the attitude of those who supported the use of the bag and bipolar version. But the real point of importance at the present time was the position of cesarean section. This operation in domestic practice had a place in skilled hands, but he was rather inclined to believe that they had given it rather half-hearted support. There were certain cases in which cesarean section was called for. Dr. Norris had defined the indications for it. They were: (1) A child must have reached nearly full term; (2) the child must be viable and in good condition; (3) that there must be probably a defect in delivery, either in regard to the pelvis, slightly small, or as regards rigidity of the soft parts; (4) it should be employed in women late in life who must possibly have another chance to bear a child; (5) the operation should be employed only where there had been danger of infection. He thought if one gave it out as decidedly the opinion that in cases of that sort cesarean section was indicated one would put the position of this operation on a proper basis, and in the future we might possibly be able to extend it or make its application less limited.

An Investigation of the Use of Iodine in Skin Sterilization for Surgical Purposes.—Dr. J. Wesley Bovee of Washington, D. C., summarized his observations and experiments as follows: 1. So far as could be ascertained by culturing epidermic scrapings, weak dilutions of iodine, even to 5 per cent. of the official tincture, thoroughly sterilized the surface of the skin for a period of time lasting from two minutes after its application to fifteen min-

utes after. While this inhibitive action of absolute alcohol was quite potent, this property was greatly enhanced by the addition of iodine to an equivalent of 5 per cent. of the U. S. P. tincture. 2. Pubic hair placed in iodine dilutions of 5, 10, 20, 30, and 40 per cent. strength (of official tincture), respectively, for two, three, five, eight, ten, twelve, and fifteen minutes, respectively, all showed growths after three days' incubation, while using 50 per cent. dilutions under the same conditions practically always prevented growths. 3. Control scrapings of skin taken from the abdomen above the umbilicus over periods of time varying from two minutes to two hours, when 40 per cent. dilutions were used, always showed negative results as to colonies. 4. Cultures from hair and skin that had been subjected to 50 per cent. dilution of tincture of iodine never produced growths. 5. Tincture of iodine diluted with an equal amount of absolute alcohol might be considered reliable as a local application in preparation of the skin or mucosa in any part of the body. Dilutions of less strength were unreliable if hairs or large hair follicles were in the field of operation. 6. The 50 per cent. dilution of tincture of iodine, if not carelessly applied, was not liable to injure the skin.

Dr. Edwin B. Cragin of New York said he was a strong advocate of iodine after the other methods of sterilization had been employed. He did not think that one ought to rely on it entirely, as some men were inclined to do, but should use it as an additional safeguard. He had used it for a year past and had been very favorably impressed with it.

Dr. I. S. Stone of Washington, D. C., said there could be no two opinions in Washington with reference to the use of iodine for sterilizing the skin. He knew of nothing which had been so satisfactory as an antiseptic to the skin. He had reduced the strength to 25 per cent. If he could sterilize catgut better with iodine than with any other sterilizing agent, short of heat, surely its penetrating qualities should be an indication for its use on the skin. He had never seen a case in which iodine had been used where the wound had broken down. There had been some cases where there was superficial separation of the wound. This might have been from subsequent contamination; it might have been from the catgut, but he had never known a deep-seated separation of the wound to occur since he had used this method.

Dr. Brooks H. Wells of New York had employed iodine in a good many hundred cases in his service at the Polyclinic with uniformly good results. He had not had any cases where there was serious irritation of the skin, and he had not had any case of superficial necrosis.

Dr. A. Lapthorn Smith of Montreal stated that he had used iodine for sterilizing the skin with very satisfactory results. Occasionally he had used it in emergency cases during pregnancy, and in a few other instances where he had had to operate quickly, and the results were just as good as if he went through the many different preparations advocated by others.

Dr. B. M. Anspach of Philadelphia stated that at the University Hospital, in the service of Dr. Clark, for a year and a half they had been using iodine for sterilizing the skin. The method they used at first was to have the patient take a general bath before the day of operation, paying particular attention to the umbilicus and pubes, then to dry the skin thoroughly and apply the official tincture of iodine. A dressing was applied over this by the nurses, and the application was repeated on the following morning. With a 10 per cent. solution or the official tincture they had seen an extensive blistering in some cases. This was painful and prevented the operation from being carried out when anticipated. Since that time they had reduced the strength to 5 per cent. and had employed the same method entirely, not using alcohol or bichlorid of mercury preliminary to the application of the iodine. They had used iodine in a series of about four or five hundred cases with gratifying results.

Dr. J. M. Baldy of Philadelphia stated that he had a profound mistrust for anything which relegated to the shades water and soap and the nail brush. Those gentlemen who had been using iodine for sterilizing the skin were getting perfect results, according to their statements. On the other hand, the same gentlemen who had been practicing surgery for fifteen or twenty years to his knowledge had made equally positive statements in regard to the value of past methods. What had prompted them to change to the use of iodine? Did they tell the truth about past methods? If they did, why were they changing and looking around for new drugs? He must say, there was a heap of mistrust in these discussions as regards the actual truth of what they were talking about.

Dr. Leroy Broun of New York stated that he had used iodine at the Women's Hospital, and had done so for ten months, although he had gotten no better results by using it than he had been getting before. The results before its use were satisfactory.

Dr. Lewis S. McMurtry of Louisville believed that all the gentlemen who were using tincture of iodine for skin disinfection could obtain the same results by much simpler and easier methods than by the iodine treatment. For instance, last summer he made a vacation visit to the Mayo clinic. Some of the patients prepared for abdominal section were painted with tincture of iodine (50 per cent. solution) in one room, and the operations were done in the other room; other patients were treated in the ordinary customary way which was now in vogue by surgeons everywhere, simply cleansing the skin without nail brush and without traumatising the skin. The patient received a warm bath the day before. The skin was washed off with soap and water the night before, and then, when the patient was brought to the operating table, he or she received another cleansing with soap and water, and the results were the same by the two methods. There was no advantage whatever in the germicidal treatment of the skin by tincture of iodine. This was tested in a series of more than one hundred cases by the Mayos in each room, and the results were the same by both methods.

A Further Contribution Concerning the Frequency and Clinical Significance of Funnel Pelves.—Dr. J. Whitridge Williams of Baltimore drew the following conclusions: 1. In typical funnel pelves the distance between the tubera ischii was reduced to 8 centimeters or less, while the usual measurements remained unchanged. 2. Such pelves were noted in 6.1 per cent. of 2,215 consecutive full-term labors, were of equal incidence in white and black women, and sometimes gave rise to serious dystocia. 3. The funnel pelvis was the most common abnormality in white women, in whom it constituted 44 per cent. of all deformed pelves. In colored women, on account of the incidence of the more unusual types, it was relatively less important, and stood fourth in order of frequency. 4. The prognosis depended not so much upon the actual narrowing of the pubic arch or upon the distance between the tubera ischii as upon the relation between it and the posterior sagittal diameter. 5. Moderate degrees of dystocia could frequently be overcome by placing the patient in an exaggerated lithotomy or an exaggerated Sims' position. In either event the antero-posterior and posterior sagittal diameters underwent an average increase of 1.62 centimeters, which so increased the available space as to make spontaneous labor possible. 6. Such an enlargement afforded an explanation for the successful outcome of certain low forceps operations which appeared theoretically impossible from the measurements taken in the usual position. 7. Pubiotomy was the operation of choice in cases of pronounced dystocia, as it not only effected the

delivery of the child, but led to a permanent increase in the size of the outlet, which might be further enlarged by the softening of the fibrous union under the influence of the hyperemia incident to pregnancy, and thus made possible the spontaneous termination of subsequent labors.

Dr. Edward Reynolds of Boston stated that the inferior strait of the pelvis was of vastly more importance than the gynecologist had supposed, and was probably of more importance than the superior strait. Dr. Williams had had the courage and intelligence to throw the traditions of the past overboard and approach the obstetrical pelvis from the point of view of common sense and sound mechanics.

Dr. Edward P. Davis of Philadelphia desired to call attention to the fact that in cases of dystocia from funnel-shaped pelvis, where the obstetrician was called in consultation because the family physician could not secure expulsion of the child, or found it difficult to extract it, the instrument slipping, and the head of the child being low down, it was the duty of the practitioner to perform craniotomy, as such cases could not be treated safely in any other way.

Diagnosis and Treatment of Contracted Pelves.—Dr. J. M. Munro Kerr of Glasgow, Scotland, stated that the diagnosis of contracted pelvis was not difficult, and the greater the deformity the easier the diagnosis. A careful measurement of the pelvis, both by the hand and by a pelvimeter, should be made. An estimate of the size of the child's head should be attempted both by palpation and cephalometer. The relative size of the head and pelvis should be estimated, and that should be the basis of treatment. Whenever possible this examination should be made in the thirty-sixth week and again at the beginning of labor if the pelvic deformity was of medium degree. To obtain the best results in the treatment of contracted pelvis it was essential that the accoucheur should be able to form a correct estimate of the relative size of the pelvis of the mother and the head of the child. He must be able to predict whether or not spontaneous delivery was likely to occur. One of the most striking features in connection with the treatment of contracted pelvis was the prominence given by all recent writers to spontaneous delivery. In no country was this more noticeable than in Great Britain, where forceps had been so extensively employed for many years. As illustrating the successful results obtained by spontaneous delivery, he exhibited a table of all such cases that had occurred in his clinic during the last two and a half years. The table showed that spontaneous delivery was quite frequent with a conjugata vera of 9.3 cm. He had twice seen a child born spontaneously, even with a pelvis of 7.5 cm., but no such case had occurred in his clinic during the last two and a half years. He reported 130 cases of contracted pelvis treated by forceps. The fetal mortality was 50 per cent., with a conjugata vera of 7.5 cm.; 33 per cent. with a conjugata vera of 8.1 cm., and 15 per cent. with a conjugata vera of 8.7 cm. He had performed craniotomy seventeen times in the last two and a half years. With reference to pubiotomy, he had had to fall back upon this operation three times, and symphyseotomy once. All these cases did well; all the children did well. He considered pubiotomy an excellent operation, but said it had a very limited field. Cesarean section was dangerous in suspect cases. In suspect cases the maternal mortality was 17.3 per cent., and if frequent examinations had been made it ran up to 34 per cent. With such a figure it was quite obvious that ordinary cesarean section was hardly justifiable. If cesarean section was performed in the suspect cases, undoubtedly the best results were obtained by removing the uterus.

Dr. J. Whitridge Williams of Baltimore noted with interest the number of spontaneous deliveries reported by the essayist, which was somewhat less than the number in his hand. In the 2,200 cases upon which his article on funnel-shaped pelves was based, there were 16 per cent. of spontaneous deliveries in all classes of inlet contractions in white women as compared with 81 per cent. in black women.

Dr. A. Lapthorn Smith of Montreal stated that the author of the paper had sounded an important note to the teachers of obstetrics both in this country and in the old country with reference to teaching young men to take more time and to allow nature more time to effect delivery in these cases of contracted pelvis. The tendency to hurry matters in these cases was a curse rather than a blessing, and it came about very largely from conditions peculiar to this country.

Dr. Richard C. Norris of Philadelphia said that his attitude towards inducing labor in properly selected cases not more than two or three weeks before the calculated term would add to the table of spontaneous deliveries given by the essayist. It was in this class that induced labor should be considered. The question of transperitoneal and intraperitoneal cesarean section had never appealed to him. He believed that craniotomy was yet a conservative operation, which must be used in certain instances. He had twice in the past year been called upon to perforate the head of the living child.

Dr. Henry D. Fry of Washington, D. C., stated that in that city they had a large colored population and he had noticed in examining a large number of pelves that fully 50 per cent. of the women had justominor pelves.

Dr. John O. Polak of Brooklyn said that his results from premature labor had been unsatisfactory. The fetal mortality had been considerable, and it had subjected his patients to the possibilities of infection. He and his associate had done cesarean section in sixty-one cases without a death, and many of these patients were handled and brought in off of the ambulance after several attempts at delivery with forceps had been made. He had had no difficulty in delivering these women, and he had had no marked morbidity, and no mortality.

Dr. Robert L. Dickinson of Brooklyn said there was a large field for the induction of labor. He did not allow primiparæ to run overtime unless they had been well starved. Starvation and early delivery had given him successful results so far as the fetal death rate was concerned.

Dr. Edward P. Davis of Philadelphia said, with reference to the cesarean section, when a woman had had a test of labor and had a contracted pelvis one needed not necessarily wait for labor, but should resort to cesarean section and in clean cases would get good results.

Salpingostomy in Pregnancy.—Dr. George Gellhorn of St. Louis said that the occluded tubes were extirpated by the majority of operators. In a minority of instances, however, where the patient desired offspring, a plastic operation might be performed with safety. This operation was devised by A. Martin of Berlin in 1885, and was termed salpingostomy. It consisted either in a resection of the peripheral portion of the tube or in an incision through the occluded fimbriated extremity, together with fixation of the everted flaps to the serosa of the tube by means of a few fine catgut or linen sutures. He reported a case in which the left adnexa were removed and the right tube split open. The patient gave birth to a healthy child three and a half years later and was about to be confined for the second time. All pus tubes caused by infection with streptococcus and staphylococcus should be removed radically. On the other hand, in tubal occlusion caused by ectopic pregnancy, or chronic appendicitis; furthermore, in hydrosalpinx of moderate extent, and hematosalpinx, salpingostomy was indicated. To prevent the recurrence of occlusion after salpingostomy he recommended an appropriate after-treatment, mainly by the use of high degrees of dry heat. If the plastic operation was thus re-

stricted the patient would suffer no ill effects, even though a certain percentage of the tubes might again become sealed.

Dr. Thomas J. Watkins of Chicago said he had recently been interested in the technique of salpingostomy, having had trouble in making an artificial opening in the tube to avoid constricting it. Even in cases where the incision was made parallel, where the mucous membrane was turned over into the serosa and stitched, and after the operation was completed the opening was surprisingly and disappointingly small. Of late he had modified the technique, which would seem to be a great advantage, namely, making a longitudinal incision, beginning at the distal end of the tube and suturing the mucous membrane on either side to the ovary, and in that way offering hope of not constricting the tube and of its not becoming occluded.

Dr. Franklin H. Martin of Chicago stated that for three or four years, instead of doing salpingostomy in these slightly sacculated cases, he had been in the habit of employing a method of opening the tubes and rendering them patulous by means of hydrostatic pressure. Any tube that would hold from ten minims to half an ounce of fluid should be treated in this way. The tube was brought to the surface, and, after being liberated from adhesions, was placed upon a thick laparotomy gauze sponge, and then the tube was milked in the direction of the fimbriated end. Almost every one of these tubes would rupture at the fimbriated end, opening up the tube along the fimbria, and at the same time causing evacuation of the tube.

Salpingitis.—Dr. Frank T. Andrews of Chicago said that salpingitis was not a disease by itself. It was a part of a general pelvic inflammation. It was referred to as an entity because of the distressing symptoms and dire consequences which followed if the infection reached the tubes. The field of action was not the pelvis alone; the forces were not test-tube bearers and the limitations to action were many. Pelvic inflammation in the majority of cases began as an acute vulvar or vaginal or uterine infection, with a tendency to spread through the tubes to the pelvic peritoneum. The infecting agent might be the gonococcus, streptococcus, members of the colon bacillus group, pneumococcus and staphylococcus. Each variety, having its many grades of virulence, varied also in the intensity of its virulence as the case proceeded. Patients differed in their power to resist or combat infection, and this resistance was not a fixed state, but changed constantly during the progress of the disease. Operators knew well the changes that had been taking place in the tubes by which the uterine and abdominal ostia became sealed. The tube was now an abscess sac, increasing in size and weight. By reason of weight it sank by a backward rolling movement toward or into Douglas' pouch. The weak place in the sac was the point where the fimbriæ were glued together to seal the abdominal end. Some quick movement or the gradually increasing pressure caused a rupture at this weak spot, and pus escaped into the pelvic cavity. Peritonitis ensued, but it was local. The patient was in bed with pain and temperature for a few days, and then was as well as before the rupture until the next attack, due to another rupture. In some cases such leakages were frequent. An operation in this case would disclose the conditions described.

Dr. Seth C. Gordon of Portland, Maine, said that pyosalpinx was very much more common years ago than it was now. In the early days of gynecology in America almost every practitioner wrapped a probe with cotton, dipped it in some solution, and passed it around the uterus. He found a number of cases of pyosalpinx in those days. Occasionally he found it following an abortion, when the tube would become very large and adherent to the vault of the vagina. He operated upon most of these cases through the vagina, making a free incision and establishing drainage, and nearly all these patients got well.

Dr. Edward Reynolds of Boston said that in many cases of chronic vaginal discharge, as soon as the tubes were dealt with the vaginal discharge decreased. This was certainly very true in his experience. He was inclined to believe it was due to the probability that in chronic salpingitis there was a passage downward of small quantities of discharge or of a ferment, which, on emerging into the uterus or vagina, kept up a much more profuse discharge in the larger passages, the tubes acting as reservoirs for the ferment, thus increasing the vaginitis, and after its removal the tubes were clear.

Dr. Thomas J. Watkins of Chicago said that Dr. Andrews' paper was along the line of developing immunity, and he had said that a patient did not get well because the local disease got better, but the local disease got better because the patient developed a general immunity. And this had been the idea in the treatment of pelvic infections. Now the gynecologist did everything he could to develop immunity. He had found that if he drained a pus tube or took it out in the most surgical manner, without spilling the pus, the patient's temperature was not shortened. The patient ran a fever for two or three weeks, probably a little longer with an operation than without it, because the amount of bacteria and poison removed by the operator was less than the amount of physiological resistance cut down as the result of the operation. So in these cases the surgeon had very much to be thankful for in this contest between physiological resistance and bacterial invasion.

Double Ovarian Dermoids in Pregnancy.—Dr. Walter P. Manton of Detroit said that in the total number of cases collected there were twenty-seven double tumors noted in the non-gravid, and seventy-three single and nineteen double associated with pregnancy. In the non-gravid, twenty-three tumors were situated on the right side and sixteen on the left. In the pregnant, of the single growths eleven were on the right and ten on the left side. From the fact that, even with double tumors, menstruation was unaffected, or showed only slight disturbance late in the disorder, it appeared that these growths had little influence on that function, and from the number of reported pregnancies did not as a rule prevent conception. On the other hand, their existence was always a menace to the health and even life of the mother during pregnancy, and especially following delivery, from the peculiar liability of dermoids to twisting of the pedicle, and in occasional instances during gestation, to the pressure caused by the size and position of the associated cyst. The coincidence of other new growths of the pelvic organs and dermoid cysts added still greater danger to the maternal host, the two morbid products not infrequently becoming formidable complications in pregnancy, labor, or the puerperium.

Dr. Thomas J. Watkins of Chicago said that with a double dermoid it would seem very feasible to simply leave a part of the tumor which retained the corpus luteum, and this probably would prevent the interruption of pregnancy. He was making some experiments along this line, but they were not far enough advanced to be conclusive.

Dr. Brooks H. Wells of New York stated that the removal of these ovaries during pregnancy did not interrupt pregnancy. He recalled a case in which there were two dermoid cysts of both ovaries, which were removed, the patient being advanced four months in pregnancy and going on to term.

Dr. Manton in closing stated that in all of these cases he personally had never had a case on which he had operated on both sides during pregnancy, removing the dermoids. In all reported cases, where the dermoid was on one or both sides, pregnancy had gone on uninterrupted The majority of operators advocated leaving behind a portion of an ovary.

Some Advances in Obstetrics During the Last Twenty-five Years.—Dr. A. Lapthorn Smith of Mon-

treal stated that if one were to ask any practitioner with a large obstetric practice what had been the greatest advance in that department of medicine during the last twenty-five years he would reply, without hesitation, asepsis and the abolition of puerperal fever. Every doctor and every nurse felt that it was now a personal disgrace to have a case of puerperal sepsis on their hands, and yet he was convinced that in many of the cases he had been called to they had been absolutely blameless. The speaker then discussed inversion of the uterus, the abandonment of ergot, injuries to the soft parts, the use of forceps, the preliminary placing of the perineal stitch, the repair of old lacerations of the cervix and perineum at the next confinement, pelvimetry, delivery by cesarean section, cesarean section for ventrofixation, puerperal convulsions and the toxemias of pregnancy, vomiting of pregnancy, spinal and other anesthesia, the use of anesthetics for the second stage of labor, and lastly the trained nurse in obstetrics.

The Blood Supply of Uterine Myomata, Illustrated with Lantern Slides.—Dr. JOHN A. SAMPSON of Albany, N. Y., stated that in his paper he presented observations from a study of eight injected uteri containing myomata. He spoke of the methods of study, arterial and venous injections, and presented photographs and enlargements, saying that the latter would show details that were not readily seen in the enlarged photographs, and he also spoke of the use of salts impervious to the *x*-ray, radiographs, and stereoscopic radiographs, etc. By means of stereoscopic radiographs of serial sections of any specimen, in which either of the arteries or veins were filled with a substance impervious to these rays, it was possible to follow the entire course of each vessel so injected. The blood supply of the normal uterus, the main intrinsic uterine arteries, to which the name arcling might be given, penetrated the anterior and posterior uterine wall and lay between the outer and middle third. Their course was horizontal in the lower portion of the body of the uterus, and obliquely horizontal (upward) as one approached the fundus. Each arcling artery terminated in a medial, radial, or centripetal branch and peripheral branch, the latter often anastomosing with a similar branch of the opposite arcling artery, thus establishing a communication between the two main arteries. All along the course of each arcling artery, radial branches arose which terminated in the endometrium, and also peripheral branches arose which nourished the myometrium. Sections of injected uteri containing myomata showed that all tumors of an appreciable size had an arterial blood supply which varied greatly in different specimens, and in the large tumors was frequently greater than that of the myometrium. These same sections failed to demonstrate any vein in many of the tumors; in others a few small veins might be seen throughout the tumor or about its periphery, while occasionally they were quite evident, but never as abundant as in the myometrium.

Anatomical Study of the Ovary.—Dr. JOHN G. CLARK of Philadelphia gave a talk on the anatomical study of the ovary, which was illustrated with numerous lantern slides. He referred to the development of the ovary from the Wolffian body. The differentiation of sex was early determined by the radical differences in the blood supply to the primitive ovary and testicle. Upon the ovarian vascular distribution apparently depended the proper development and maturation of the Graafian follicle. He traced the successive stages of development of the ovary from infancy to old age. The corpus luteum was of the greatest importance, and nature has devised a very comprehensive vascular scheme for its development and retrogression. Upon the maintenance of the vascular system of the ovary apparently depended the perpetuation of the menstrual life of the individual.

The Function of the Ovary.—Dr. ROBERT T. FRANK of New York drew the following conclusions: 1. Both from anatomical evidence and functional behavior the active portion of the corpus luteum must be regarded as an epithelial structure. 2. A sharp distinction should be drawn between proestrum and estrum (menstruation was the homologue of proestrum). 3. Proestrum and maturation of follicles coincided in all mammals, but as yet no proof had been forthcoming that maturation actually caused proestrum. 4. The period of desire (estrus) was the climax of the preparatory changes occurring during proestrum and probably due to the same causation. 5. Ovulation was the end result of follicular maturation. In some species it occurred during or immediately after estrus; in others the bursting of the follicle was postponed for months. Such differences in time relation were most probably accounted for by the rate of growth from the ovum and follicle. (a) Ovulation might be accelerated by coitus. (b) Ovulation was inhibited by the corpus luteum. 6. (a) The corpus luteum sensitized the uterine mucosa and thus rendered it responsive to mechanical stimuli, with resulting formation of maternal placenta. (b) The corpus luteum was essential in the early part of pregnancy and the ovum failed to obtain a foothold unless the uterus was sensitized. (c) The corpus luteum lengthened the cycle by interfering with the maturation of growing follicles and ova. (d) The factor which caused the persistence of the corpus luteum during pregnancy had not been discovered. Persistence of the corpus luteum might also be found independent of gravidity. 7. Animals with interstitial glands in their ovaries might ovulate spontaneously, consequently the interstitial gland had not been shown to replace the function of the cylical corpus luteum. 8. Growth of the mammary gland was due to ovarian influence (maturation of follicles, activity of corpus luteum). The same factors which produced the persistence of the corpus luteum probably caused the breast hyperplasia of pregnancy.

Is There Any Clinical or Experimental Proof That the Ovary Has an Internal Secretion?—Dr. W. H. MORLEY of Detroit, Mich., stated briefly that from the experimental reports, from the clinical investigations, and from the anatomical and histological data gleaned from the literature and from personal experience, the following tentative conclusions seemed justifiable: 1. The ovary possessed an internal secretion. 2. The internal secretion was produced by the corpus luteum. 3. In so-called ovarian insufficiency relief might be obtained with an extract of the corpus luteum. 4. No untoward symptoms resulted from its use in conditions where it was indicated, even if no relief was obtained. 5. The extract should be properly prepared and given a fair trial before it was discontinued.

Conservation of the Ovary.—Dr. W. W. CHIPMAN of Montreal, said that the loss of the ovaries meant the loss of sex influence to the individual with all the grave disturbances in general metabolism which this loss signified. The earlier in life that it occurred the greater was the calamity. Ovarian transplantation sought to replace the lost or disabled gland. In animals this procedure had been so successfully carried out that conception had followed it, even in heteroplastic transplantation. In the human subject only one such case had been reported, that by Robert T. Morris, although in homoplastic transplantation Morris and Frank had both reported cases. In homoplastic transplantation the cases must be few wherein an ovary in whole or in part was healthy enough to be removed and engrafted, and was not healthy enough to leave alone. In this connection it was wise to remember the value of the ovarian ligament, for this frequently contained active parenchyma tissue. It was also generally believed that the ovary possessed considerable capacity for regenerative tissue after its partial removal, and hence an additional reason for leaving the segments *in situ*. In selected cases the ovarian extract had a definite therapeutic value, al-

though the results in different individuals were by no means uniform. He had seen no ill effects follow its use, and in some instances the results were almost miraculous. A single instance of a case seen some three months ago might be cited. This was a young woman of twenty-seven, from whom both ovaries had been feloniously removed for dysmenorrhea two years before. The condition of this woman was pitiable, and the close correlation of the ovaries to the sympathetic system was amply borne out by her appearance. A state of chronic surgical shock, with pronounced mental instability, perhaps best described it. The exhibition of two 5-grain tabloids of "varium" three times daily recreated this woman within a month. In some cases he had found that the addition of arsenic or small doses of the thyroid extract gave more favorable results. The natural and proper conservation of the ovary consisted in leaving it alone. As a society we could not too strongly fortify this position, and especially as concerned the woman in her second or third decade.

Behavior of the Ovary after the Removal of the Uterus.—Dr. Robert L. Dickinson of Brooklyn stated that conservation of ovarian structure after hysterectomy showed four-fifths of the patients free from disturbances of the surgical menopause. The results were somewhat better where both ovaries remained than where one was left or where resections were done. Where the disturbances had occurred their character was less severe and more gradual than after bilateral removal of the ovaries. In married women the conservation showed nearly uniform persistence of sexual desire. The practice of removing ovaries when taking out a uterus at or near the time of the menopause was strongly opposed, except in cases of malignant disease or when infected. Conservation after operations for incurable tubal infections left more tender and troublesome ovaries than after hysterectomies for fibroids, prolapse, or the hemorrhages of chronic metritis. After removal of the uterus, particularly of one ovary, or a large fibroid, ovarian edema or hypertrophy was frequent. The menopause was likely to occur earlier than the average time in a woman who had lost her uterus. To preserve the functional activity of the ovary its circulation must not be impaired. Removal of the tubes frequently compromised the ovarian blood supply, and was a delicate and unnecessary adjustment. Barring disease and closed tubes and malignancy and tuberculosis, they should be disregarded and allowed to remain. In forty cases in which both or one remained behind, he could not see that any harm had resulted.

The End Results When Hysterectomy Has Been Done and an Ovary Left.—Dr. John Osborn Polak of Brooklyn drew the following conclusions: 1. The technique of the operation and the general health of the patient had much to do with the end results. 2. A conserved ovary, if unhealthy, would leave the patient in a worse state mentally, nervously, and physically than if a total extirpation had been made. 3. When the woman was at the age in which the menopause should occur, or when she was past the menopause, a total ablation gave the best results. 4. The nervous phenomena were more marked when the patient was operated upon, when she was in comparatively good health, with a high preoperative blood pressure, than when the blood picture showed anemia or toxemia. 5. The symptoms of the operative menopause were less after extirpation for pelvic inflammation than when the ablation was done for fibromyomata. This was probably due to the associated vessel changes which were found in fibrosis. And finally, when one or both ovaries were healthy they should be conserved, and the younger the patient the more necessary was conservation.

Ovarian Transplantation in Lower Animals: Review of the Literature.—Dr. Franklin H. Martin of Chicago drew the following conclusions. 1. His work and the work of Mauclaire, Marshall, Jolly, Sauve, and Casalis and others on human females, and the work of Pankow and Sauve on animals, clearly demonstrated that there was a definite antagonism between the blood or the tissues of one individual and that of another to an ovarian graft. 2. The work of Pankow and Sauve seemed to show that this lack of homogeneity of conditions existed between animals closely related by consanguinity. 3. On the other hand, his experience and the reported work of Casalis, Sauve, Marshall and Jolly, Mauclaire, Pankow, and others demonstrated that there was practically no antagonism between the blood or tissues of an individual to ovarian graft from her own ovaries. 4. As the lack of success in transplanting ovaries from one individual of the same species to another was not one of technique apparently, but one of tissue or blood antagonism, would it be possible for us by some process of preparation of patients to render the blood or the tissues of the donor and recipient homogeneous, and thus make more successful tissue transplantation?

Dr. Seth C. Gordon of Portland, Maine, believed that when they were obliged to remove both ovaries they should always remove the uterus along with them. He did not know of any condition by which they could justify themselves in leaving the uterus after the ovaries were removed.

Dr. A. Lapthorn Smith of Montreal stated that the unfortunate part of his professional experience had been so-called conservative gynecology. He was a happy operator before he began conservative work on the ovaries.

Dr. W. Gill Wylie of New York stated that what was done today was a great improvement on the past, and he would accept most of what had been said by the authors of these papers; still the experience of some of them who were older in the profession had had a bad effect in one way and a good effect in another; that was in the days when Battey proposed the removal of normal ovaries for dysmenorrhea, hemorrhage, and other conditions; they were even then cured. In those days he removed the ovaries for reflex troubles in some cases, but in very few. The reason he did not do more of these operations was because he had found imperfect development had a great deal to do with the ovary, and that a faulty development of the ovaries had much to do with the growth and development of the woman, not only as to how she menstruated, but as to the effect on her growth.

Dr. Walter P. Manton of Detroit, Mich., stated that he was the first in the Middle West, he believed, to take up the conservative treatment of ovaries. Years ago he published a list of one hundred cases on which he had operated in a conservative manner and followed them carefully, and he found in that number a little over 94.6 per cent. of somatic cures and 5.6 per cent. of the women afterwards become pregnant. Since that time he had continued this conservative work satisfactorily, and the somatic cures had remained about the same.

Dr. Edward Reynolds of Boston said he had been working along the lines of conservatism in the treatment of the ovaries for a good many years, and he found that the conservative management of these cases, and the institution of operations for the correction of minor pathological conditions in the ovaries had grown upon him steadily, so that to-day he believed it was practically never necessary to remove all the ovarian tissue from a woman of child-bearing age except in cases of malignancy, or tubo-ovarian abscess, or extreme inflammatory disease.

Dr. J. M. Baldy of Philadelphia said with reference to the internal secretion of the ovary, until absolute and unmistakable proof was furnished along this line, he did not propose to base his surgical methods and the health of his patients on any such nonsense.

Dr. George Gellhorn of St. Louis stated that he had used ovarian extract for a number of years, and frequently in patients who had reached the menopause, both natural and artificial, and his results had not been uniform, nor were they convincing. In the menstrual disorders of puberty the results had been a trifle better but not constant.

Dr. Thomas J. Watkins of Chicago said he could see no logical reason for removing a normal ovary, but he could see much logical reasoning for leaving parts of diseased ovaries, especially in young women. He had left parts of suppurating ovaries, and he had never left part of a suppurating ovary that had given any trouble afterwards, the sac of the abscessed ovary being very thoroughly excised.

Dr. I. S. Stone of Washington, D. C., stated that there was cause occasionally for leaving the uterus after the removal of the ovaries The uterus was left frequently for the purpose of repair of intestinal injuries. It ought to be and could be used in that way. He knew of nothing in his surgical work with reference to the saving of human life which had given him more satisfaction than conservative surgery upon the ovaries.

Dr. Joseph Brettauer of New York stated that he had had a good deal of experience with the administration of ovarian extract which came from the market, with practically no results in hundreds of cases. He had had most gratifying results in fighting the disagreeable symptoms accompanying the climacteric with very small doses of thyroid which surely was not derived from the ovary. As to conservative surgery, he was extremely loath to open the abdomen, but when he did open it, he was very rarely conservative.

Dr. Frank T. Andrews of Chicago stated that for some time he had held that every rupture of a follicle consisted of a spontaneous inoculation of the patient, and was followed by a small amount of inflammation within the pelvic cavity, and that there was a sort of response on the part of the tissues of the patient. If the spermatozoa passing into the ova exerted an influence on the female, and they got future development and maturation of the ovum, that furnished to the female the one thing which was needed to make a great many changes in the body. It furnished the ambocepter and allowed the working of Ehrlich's side-chain theory, and therefore, they had not an internal secretion, but a doubleheaded internal secretion, a combination of substances that brought about all changes in the site of attachment of the ovum in the uterus. The changes in the ovary led to the changes in the corpus luteum, changes in the breast and general physique of the patient.

Dr. Lewis S. McMurtry of Louisville stated that he was sure every man present, when at the operating table, would deal with ovarian diseases in practically the same way. Some of the speakers had discussed inflammatory diseases. They had alluded to adhesions, and they were going to deal radically with all those cases in which there were longstanding acute infections, and they were going to remove infection and remove useless organs. Others had been talking about moderate degrees of cystic degeneration, which was an entirely different subject both from a pathological and surgical standpoint, so that he was satisfied that those who had spoken would all do practically the same thing.

Dr. J. Whitridge Williams of Baltimore said in connection with the corpus luteum, when associated with the condition of hydatidiform mole, they frequently had tumors arising from the corpus luteum of very large size. They got double cystomata of the ovary, multilocular cystomata of the size of his two hands developing on either side. These cystomata were made up of cysts, of varying size, many of them reaching an inch and a half in diameter, lined by lutein cells. Whether they were the cause of the hydatidiform mole, or whether the hydatidiform mole brought about their production, he was not prepared to state, but an interesting point was this: recent observation showed that many of these cases, if followed for a reasonable time, after extrusion of the mole, underwent absorption, and there were a number of cases where tumors larger than a cyst had disappeared within six months after extrusion of the mole.

Dr. J. M. Munro Kerr of Glasgow, Scotland, stated that they were all agreed that there were certain cases in which the ovary should be conserved. On the other hand, in cases of malignant disease of the uterus, and suppurative conditions of the adnexa, it would not be considered good surgery to conserve ovaries. In such cases the uterus, tubes and ovaries should be completely extirpated.

Vaginal Cesarean Section in Eclampsia.—Dr. Reuben Peterson of Ann Arbor, Mich., discussed in his presidential address vaginal cesarean section in the treatment of eclampsia, based upon a study of 530 published and unpublished cases. He drew the following general conclusions: (1) The maternal and fetal mortalities were lower, the earlier the uterus was emptied after the first convulsion in antepartum eclampsia. (2) Hence no time should be lost in employing the slower methods, but as soon as the diagnosis of eclampsia was established, the uterus should be emptied by the operation which would give the best results for mother and child. (3) Vaginal cesarean section met these requirements because it was based upon sound surgical principles, was quickly performed, while its technic could be acquired by anyone familiar with the rudiments of obstetric surgery. (4) Early diagnosis and early operation in antepartum eclampsia would lead to a marked reduction in both the maternal and fetal mortalities.

Dysmenorrhea Relieved by Nasal Treatment.—Dr. Joseph Brettauer of New York called attention to a monograph published in 1897 by Dr. Wilhelm Fliess in which he claimed that certain spots in the nasal mucous membrane, the tuberculum of the septum, and the anterior half of the lower turbinate had a direct connection by way of the sympathetic system with the genital organs. During menstruation these circumscribed areas were invariably swollen, more prominent, hyperesthetic, and bled easily upon the slightest touch, all of which symptoms disappeared after cessation of the menstrual period. In cases of severe dysmenorrhea, the symptoms—nausea, vomiting and pain in the iliac regions—had immediately disappeared upon the application of a twenty per cent. solution of cocain to the genital spots. Whenever such prompt relief was obtained, permanent relief was often secured by cauterization of the genital spots during the menstrual interval, with trichloracetic acid, the galvanocautery or bipolar electrolysis and by attention to any pathological condition found in the nose. The accuracy of these claims had been substantiated at several clinics and they had been endorsed by Schiff and others. He had had remarkable results in several instances by this treatment, and in his paper he cited the histories of five cases in detail.

The Pelvic Kidney.—Dr. J. Dougal Bissell of New York presented a further contribution to the study of pelvic kidneys and their replacement, and reported two new cases.

Anteflexion of the Cervix and Spasm of the Uterine Ligaments in Relation to Retroversion, Dysmenorrhea, and Sterility.—Dr. Edward Reynolds of Boston stated that for about eight years the muscular character of the so-called uterine ligaments had seemed to him of clinical importance in connection with the constantly accumulating evidence of the frequency of their spasms, which he had observed in the course of clinical work. His paper dealt

at some length with the anatomy of these so-called ligaments and with the evidence of their muscular character as described in anatomical literature. This was frequently perceptible in dissections made during life, namely, during operations, but was not readily detected post-mortem except by serial microscopical sections involving considerable technical difficulties. For this reason adequate descriptions of their musculature had only recently been embodied in the anatomical textbooks, but were now almost universal. This muscular tissue existed in especially important quantities in four situations, throughout the uterosacral ligaments, and at the bases of the broad ligaments, along the upper edges of the broad ligaments, and in a sheath underlying the bladder and attaching the cervix and vaginal vault to the descending rami of the pubes. The insertion of the anterior vaginal wall into the cervix was also a uterine attachment of much importance. This wall was largely nonmuscular and was attached at one end to the cervix and at the other to the arch of the pubes. The muscular character of the uterine ligaments accorded with general zoological law which held throughout the mammalian order, that except in a very few instances in which ligaments of elastic yellow connective tissues, as the ligamentum nuchae, were especially provided, all weight-bearing function was clonic and continued, they were usually of unstriped muscular fiber. This universal law was thus proved by recent progress to be as true of the so-called uterine ligaments as it was of all the other structures throughout the body and throughout the mammalian order. His paper dealt at some length with the anatomy of conpubertal anteflexion of the cervix, and with the exaggeration of this deformity by spasm of the muscular ligaments. He believed that his observations showed that the many cases of marked anteflexion of the cervix which were free from symptoms were also those which were free from spasmodic exaggeration of the deformity, and those which were attended by symptoms were usually the subjects of much spasm. He discussed the relation of this deformity to obstructive dysmenorrhea, sterility, and to many cases of retroversion. He then described a plastic operation which he had found successful for its correction, and for the relief of symptoms in these conditions.

Exhibition of Specimens.—Dr. Philander A. Harris of Paterson, N. J., exhibited numerous specimens of gallstones and gallbladders, and made some remarks on the subject of gallstones.

Epilepsy and Pregnancy.—Dr. G. Brown Miller of Washington, D. C., stated that epilepsy had little direct influence upon the course of a pregnancy, except that traumatism produced by epileptic seizures might cause a premature labor and abortion. The influence of pregnancy upon epilepsy was of greater interest. In a certain proportion of cases the toxemias of pregnancy might influence very unfavorably the epilepsy even to producing the status epilepticus. The difficulty in making a diagnosis between the status epilepticus and eclampsia was great, but the proper diagnosis was necessary as the treatment was radically different. He reported a case of probable status epilepticus, discussed it, and reported a few similar cases from the literature. From a careful study of his own case and the literature, the following conclusions would seem to be warranted: (1) In women with epilepsy where pregnancy apparently caused the convulsions to become more frequent or more severe, one should always consider the necessity of terminating the pregnancy. (2) In cases of pregnancy in epileptic women, one should watch with extreme care for indications of toxemia or the premonitory signs of eclampsia, and should put an end to pregnancy at the appearance of symptoms of much less gravity than would indicate this procedure in women who were not the subject of disease.

Repeated Ectopic Pregnancy, with a Report of Four Cases.—Dr. Richard R. Smith of Grand Rapids, Mich., reported four cases in which a second tubal pregnancy followed a first. In two the interval was about two years; in the others but one; in two of these women these pregnancies constituted the only ones, the other two having previously borne children. He had found about 170 similar cases in the literature, to which he added these, and a number of others obtained through correspondence. In a total of 2,998 cases there had been 11 recurrences, or about 3.8 per cent. He pointed out the difficulty of following up hospital cases over a period of years to know of their welfare and the fact that age, social condition and lapse of time since operation were not taken into consideration in these figures. He believed the percentage would be higher in cases where a patulous tube was left and social conditions were favorable to pregnancy. These cases of repeated ectopic had occurred, as might be expected, in the child-bearing age and in the decades in which normal pregnancies were most prevalent. There was a high death-rate following the second ectopic, but later reports seemed more favorable and showed a death-rate apparently not higher than that following a single ectopic. In 116 cases of second ectopic, there were 101 recoveries, and 15 deaths with or without operation. The average length of the interval was about thirty months, but no rule could be formulated as to when a second ectopic might be expected. A considerable number occurred in less than six months. Baldy reported one occurring twelve years after the first. The percentage of interval pregnancies was small; most of the recurrences took place in the opposite tube, but a number were reported as recurring in the same one, also several ovarian pregnancies (doubtful), and an abdominal followed by a tubal. Several instances of three ectopics occurring in the same women were reported. He had been unable to obtain exact data in any considerable number of cases as to further normal pregnancies following an ectopic, but believed them to be less frequent than ordinarily assumed. He gave as his opinion that the matter of the disposal of the other tube should be discussed with the patient before operation whenever practicable. In young women and those desiring children the opposite tube might be saved; in those who had already borne as many as desired, it should be sacrificed rather than to submit the woman to the distressing possibilities of a second accident. The appearance of a tube when patulous was no criterion as to its capabilities.

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. Howard A. Kelly, Baltimore; *First Vice-President*, Dr. Richard R. Smith, Grand Rapids, Mich.; *Second Vice-President*, Dr. John A. Samson, Albany, N. Y.; *Secretary*, Dr. Leroy Broun, New York, re-elected; *Treasurer*, Dr. J. Wesley Bovee, re-elected.

Baltimore, Md., was selected as the place for holding the next annual meeting.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held March 9, 1911.

Dr. William Shannon in the Chair.

Hereditary Syphilis and the Wassermann Reaction, with Five Cases in One Family.—Dr. Mark S. Reuben presented these patients. On October 16, 1909, a child, one and a half years old, was brought to the Vanderbilt Clinic for treatment. The mother stated that there had been a fissure of the anus for six weeks and that there was no tendency to heal. The child had never been ill before; there were no signs of snuffles nor rash of any kind. The

family history, however, was very interesting and helped to clear up the diagnosis. The mother had been married once before, and by that marriage had conceived six times. The first child lived three years and died of scarlet fever and measles; the second child lived two years and died of cholera infantum; the third child, the fourth, and the fifth were all stillborn at full term. The sixth child was prematurely born at eight months and died within one week. Her first husband died in 1899 of cerebrospinal meningitis and pneumonia. She remarried in 1900 and by her second marriage had five children, the infant above described being the youngest of these. The physical examination of the infant was entirely negative; neither the spleen nor liver were enlarged; no glands were enlarged and there were no scars but there were some signs of a mild rickets. On the strength of the family history and the chronicity of the anal fissure a diagnosis of syphilis was made. The patient was put upon mercury internally and calomel locally. The v. Pirquet test was negative. The fissure did not look as sluggish as before and this treatment was continued. Ten days later a Wassermann test was made but was negative; however, the same treatment was continued and within three weeks after the first visit the ulcer was completely healed. On November 19, 1909, the second daughter, aged seven and a half years, was brought to the clinic suffering from a unilateral sore throat; the examination showed a diphtheritic-like deposit on the right tonsil. The cultures taken were negative. The cervical glands on that side were enlarged. Six weeks later she developed a typical roseola. On December 16, 1909, a nine-year-old child developed a throat condition similar to that of the above. On December 13, 1910, a boy was brought to the clinic suffering from mucous patches on both tonsils. On December 13, 1910, another boy was brought to the clinic suffering from sore throat and mucous patches were found. On December 20, blood for the Wassermann reaction was taken from every member of the family and with the following results:

Second husband, W.R. —. Physical examination negative.
Wife, W.R. +. Physical examination negative.
Girl, 11 years old, W.R. +. Physical examination showed mucous patches in the throat.
Girl, 9 years old, W.R. +. Physical examination as above.
Boy, 7 years old, W.R. +. Physical examination as above.
Boy, 5 years old, W.R. —. Physical examination negative.
Boy, 3 years old, W.R. +. Physical examination showed mucous patches in the throat.

Hereditary Syphilis and the Wassermann Reaction.—Dr. Mark S. Reuben read this paper. He first reviewed the literature of syphilis from the fifteenth century to the discovery of the Wassermann reaction and then discussed the effects of the discovery of this test upon preconceived ideas in regard to syphilis. He concluded as follows: "1. The most usual mode of transmission of syphilis to the fetus is through the placenta. If the infant is syphilitic the mother is invariably syphilitic also; the father may or may not have syphilis. 2. Mothers who have no syphilitic symptoms, but who give birth to syphilitic children, have syphilis in a latent form; 72 per cent. of these women give a positive Wassermann reaction. 3. Mothers with syphilitic symptoms, who give birth to syphilitic children, give a positive reaction in 72 per cent. of the cases. 4. The earlier the blood of the mother is examined after the delivery of the last syphilitic child, the greater the percentage of positive Wassermann reactions. Thus of the mothers whose blood was examined within one year of the birth of the last syphilitic child, they obtain 90 per cent. of positive Wassermann reactions; of those examined within two years they obtain 65 per cent. positive reactions, and of those examined within four years they obtain 40 per cent. of positive reactions. 5. In women with no syphilitic symptoms, who have given birth to from one to seven syphilitic children they obtain a positive reaction in 60 per cent.; if they have more than seven children they get a positive reaction in 46 per cent. of the cases. 6. In mothers with symptoms who give birth to one syphilitic child they obtain 20 per cent. positive Wassermann reactions; to those who give birth to two syphilitic children, they get 60 per cent. of positive reactions; to those who give birth to four, five, six, or seven syphilitic children they obtain 100 per cent. of positive reactions, and in those who give birth to eight syphilitic children they obtain 80 per cent. of positive Wassermann reactions. 7. The great majority of infants of syphilitic mothers are themselves syphilitic. A syphilitic mother may give birth to a syphilitic child, or during her latent stage to a healthy infant, but never to one who is immune to syphilis. Of 123 infants born to syphilitic mothers, 110 gave a positive Wassermann reaction, *i.e.* about 90 per cent. 8. Over 99 per cent. of infants with hereditary syphilis gave a positive Wassermann reaction. 9. Children suffering from late hereditary syphilis give in 50 per cent. a positive Wassermann reaction. 10. An infant suffering from hereditary syphilis may give a negative Wassermann before any symptoms are present and a positive reaction later when symptoms arise. a. Mercury and salvarsan cause a positive Wassermann reaction to become negative, but in a certain number of cases the reaction becomes positive again within six months. b. Mercury and salvarsan do not cure syphilis; they only transform an active lues into quiescent or latent lues. c. The blood of every wet nurse should be examined for the Wassermann test; if the reaction is positive she has syphilis and should not be employed; if it is negative the blood of her infant should be tested; if this gives a positive reaction, the mother should not be employed for she has syphilis, even though her own reaction is negative. 11. In women in whom syphilis is suspected and who give a history of frequent abortions, a positive Wassermann reaction is found in 87 per cent. of the cases. 12. The virus of syphilis is mild at first, increases in severity for a few years, then remains stationary, and later begins to decline. 13. Syphilitic women on the average conceive about six times, but seldom have more than 2¾ living children unless their number of pregnancies is more than six. Of all the conceptions of syphilitics 75 per cent. result in death within one year. Twenty per cent. of all pregnancies result in abortion; 10 per cent. of all pregnancies result in still births; 10 per cent., in premature births; 22 per cent. result in full term syphilitic children; 18 per cent. die within one year of syphilitic or intercurrent diseases, and only 2 per cent. of all pregnancies of syphilitic women result in healthy children."

Dr. L. E. LaFetra said that he had asked Dr. Reuben to present these patients because the family history illustrated more points than any with which he had met. The first husband presumably had the disease. There were two points in particular which Dr. La Fetra wished to emphasize. The first was the value of the Wassermann reaction in making a diagnosis of hereditary syphilis, even though there were no symptoms presented that were definitely syphilitic. The baby shown had had an ulcer at the anal margin, which was seen by several dermatologists at the Vanderbilt Clinic, and they all thought that the lesion was tuberculous. However, they still adhered to the diagnosis of syphilis. The von Pirquet test was negative. The Wassermann reaction cleared up the diagnosis. The second point which Dr. La Fetra emphasized was in regard to the Wassermann reaction in the selection of wet nurses. While it would rarely be needed it might in doubtful cases be of decided help. Infants born of syphilitic mothers gave a positive reaction in 99 per cent. of the cases; in only 1 per cent. did the reaction fail; this was certainly a very small percentage. If the reaction was present in either the baby or the mother it would be wiser, notwithstanding the slight danger to the foster child, to look for another wet nurse. Dr. La Fetra thought it safer

to use wet nurses whose babies were over six weeks old, then the clinical examination would usually be all that was needed.

Dr. Henry Koplik said that at present there was going on great discussion regarding the value of the Wassermann reaction. The question had been raised as to whether or not this test should be taken as a standard in the selection of wet nurses. If this reaction could be taken and something like uniform results obtained it would be a good thing. As yet they were not able to say with positiveness that this reaction was of great value in the selection of wet nurses. Dr. Rudolph Fischl, after an experience of twenty-five years in the selection of wet nurses, stated that he had not seen one case when he had "passed" a wet nurse on clinical grounds in which syphilis had developed in the foster child. Any clinician with his eyes open need not subject the children or mothers to this test. Dr. Koplik thought the time was premature for deciding upon the value of this test; we were not ready for it yet.

A Duodenal Tube for Infants.—Dr. Alfred F. Hess read this paper and presented a tube with which he was able to gain access to the duodenum in infants ranging from two to fourteen months of age and weighing as little as seven pounds. This tube consisted of a simple rubber tube to which a perforated leaden ball was attached. It acted by means of gravity, entering the duodenum quickly within from twenty to thirty minutes. Dr. Hess exhibited *x*-ray photographs which clearly showed the tube in the duodenum; in one of these the stomach was filled with bismuth and the metal end of the tube was below in the intestine. He also showed alkaline bile-stained duodenal juice, which was the characteristic juice of the duodenum and which might be taken as a criterion that they had passed through the stomach into the intestine. This was the first time that it had actually been shown that they could reach the duodenum in infants. Dr. Hess said that he did not as yet know the value of this new method, but it would have scientific value in investigating cases of malnutrition of infants and therapeutic measures. In practice at present its general value seemed to lie in the diagnosis of pyloric stenosis, in which, if they entered the duodenum and obtained the characteristic juice, they could rule out the presence of a marked stenosis. It could also be used in the feeding of infants who suffered from protracted vomiting where the tube could be left *in situ* and the baby fed for some days in this manner.

Dr. Max Einhorn said that about one year ago he had reported a case of stenosis of the pylorus in an infant three months of age, which was helped by stretching the pylorus. Since that time he had had occasion to introduce the instrument he presented through the pylorus and into the duodenum. After he had employed this method in the adult he conceived the idea that it was well worth trying in infants. Dr. Einhorn presented his duodenal bucket and told of its value in ascertaining the permeability of the pylorus. He had also devised a duodenal olive for use in little children which was for the purpose of determining whether or not the pylorus was permeable. The distance to the cardia was ascertained by certain measurements. After the introduction of the olive it was left in a few hours and then withdrawn; the distance from the lips to the bile stain was noted. If there was any regurgitation of bile this was shown on the thread portion lying in the stomach. Dr. Einhorn had also used a duodenal pump for infants and had succeeded in obtaining duodenal secretion. There was a control test in infants; they were allowed to suck milk while the pump was in the duodenum. In the case of a three months old infant the instrument reached the duodenum in forty minutes, when clear duodenal fluid of a golden color was obtained. To make the test positive the baby should be given milk; while suckling pure bile could be withdrawn without the admixture of milk. Dr. Einhorn demonstrated an apparatus for stretching the pylorus in children similar to that used for the same purpose in adults.

Dr. Louis Fischer said that he was much interested in the work of Dr. Hess which had been duplicated by Dr. Einhorn. The instrument was passed into the stomach as one would pass an ordinary stomach tube. He waited a little longer than did Dr. Hess. An ordinary glass syringe was then attached and the duodenal contents aspirated. If milky fluid was obtained it was presumed that the duodenum had not been entered. If one waited for from twenty-five to thirty minutes a golden yellow or greenish fluid would be obtained. Dr. Fischer reported the case of an infant, three days old, with constant vomiting and active peristaltic waves, most pronounced when food reached the stomach. The condition persisted for over two weeks. Neither casein nor fat flocculi were found in the feces. The Einhorn duodenal bucket was introduced and left in the stomach over night. When removed it was seen by the stained cord that the bucket and the cord to which it was attached had passed through the pylorus and into the duodenum for at least seven centimeters. Thus the grave doubt as to the existence of a pyloric stenosis was removed. This infant made a complete recovery under treatment consisting of daily lavage and rectal feeding.

Dr. Thomas S. Southworth did not believe it was necessary to introduce the bucket presented to tell whether or not there was true stenosis of the pylorus; clinical evidences could be obtained. If there was true stenosis there would be no milk residue in the movements.

Dr. Henry Koplik expressed wonder at the confidence that had been shown in the ability to get good results in cases of either real or apparent stenosis of the pylorus. He could not see how they could speak of treating these cases with any such confidence as had been expressed. If the pylorus was sufficiently dilated to allow the beads to pass he did not believe it was a case for dilatation. One should watch the stools to see if there was any milk residue present. Any pylorus that allowed a small amount to pass through had no spasm but was relaxed. What had been said regarding the value of these instruments seemed to him rather utopian. He doubted whether any man could say that he had passed such a sound from the mouth to the pylorus and through it in fifteen minutes; certainly not in pyloric spasm or stenosis.

Premiums for Nursing Mothers and Milk Depots for Infants.—Dr. Charles Hermann read this paper. He had made a study of this subject in France and Germany. In Berlin each nursing mother who presented herself regularly with her baby at the milk depot received a fortnightly sum in advance not exceeding $1.40 per week. The majority received from thirty-five to eighty-five cents. The object of these premiums was to encourage breast-feeding and to keep the infant under observation so that the mother might be instructed. Some thought that the percentage of nursing mothers was increased by this plan, while others did not believe that there was much if any increase in the number. Dr. Hermann did not think that the results justified the great expenditure of money. It was quite generally admitted that the mothers stayed away from the depots as soon as the premiums were discontinued. The mothers were not sufficiently educated to appreciate the value of the instruction received. If they were truly educated they would learn from their first experience how to care for succeeding children, but this was not the case; the same mothers came again with the second and third child to get the premium which was often used for purposes other than the purchase of food for the mother as was intended. Even with the premiums it was impossible to keep the mothers under observation for any length of time. Dr. Hermann thought the money could be employed to better advantage by paying visiting nurses $75 per month. Milk

depots which simply distributed milk were of little value. It was necessary to emphasize the fact that they might be harmful by diminishing the number of breast-fed infants. Even if instruction and medical supervision were added to the work of the milk depot there was usually no corps of visiting nurses or their number was very inadequate. The first milk depots were established in Berlin in 1905, and at present there were seven under the direction of well-known pediatrists. Tugendreich summed up the results as follows: "When we consider the small number of institutions, the small attendance at many places, the short period of observation, which in many cases did not admit of any beneficial results, it was not difficult to understand that a marked success of the depots was not perceptible and that there was no distinct reduction in infant mortality. It was not the fundamental idea that was at fault, but the imperfect and incomplete carrying out of the plan." Dr. Hermann called attention to the many reasons why mothers did not or could not come to the depots, and was of the opinion that sending the trained nurse into the home was a much better plan. He described the method that had been adopted at the Lebanon Hospital for following up the mothers after infants were born in the maternity wards. While still in the hospital the mothers were instructed in the care and feeding of infants. Printed forms were given to assist the memory, and also a card to the pediatric department of the dispensary with the instruction that they should return to the dispensary in ten days after leaving the hospital, or in special cases sooner. If they did not come a postal card was sent to them; if they failed to respond to this a visit was made to the home. Sick babies were to be brought to the dispensary immediately. Dr. Hermann emphasized the following points: 1. The importance of giving the mother instruction from the start. 2. Of 14 deaths seven occurred during the first month of life and five of these occurred during the first two weeks; therefore anyone who expected to see a drop in the infant mortality as soon as a milk depot was established was bound to be disappointed. 3. The milk depot should be established in connection with an out-patient department for treating babies that are slightly ill, and a hospital ward for those which were very ill. Breast milk should be provided for special cases. 4. From 75 to 80 per cent. of these mothers were able to give the breast for five or more months. Of the remainder few were too poor to buy bottled milk and could easily be taught to modify this milk. It was not necessary to distribute modified milk. 5. For the majority of cases one visit a month to the depot was sufficient; for special cases more were necessary. The city need not try the very expensive experiment of supplying modified milk for infants. The emphasis should be placed on breast feeding and not on the distribution of cow's milk of good quality.

Dr. Edwin Bradford Cragin said that the most important point to emphasize was the value of breast-feeding and the advantage of the mothers coming to the depots while still nursing their infants. The responsibility was thrown on the obstetrician who should see that the infant was kept at the breast until it got to the depot. He showed how much could be done to promote nursing in cases that seemed unpromising and even hopeless.

Dr. L. E. LaFetra said that he was opposed to all measures that reduced the responsibility of the father or mother of the family for the care of the children they voluntarily brought into the community. There was too much of a tendency to give things and do things for the poor. Instead, careful instruction should be given with the baby as the text. Encouragement of breast-feeding was of the greatest value, and his experience had been that nursing for six months could be carried on by from two-thirds to three-fourths of the women they saw at the dispensaries. The modification of milk at home for supplemental feeding and for feeding after weaning was perfectly satisfactory. Dr. LaFetra expressed himself as in sympathy with the conclusions presented by Dr. Hermann.

Dr. Josephine Baker stated that there were two points to be considered in reference to the work of the milk stations: 1. The milk stations must be supplemental to the work of visiting the mothers in their homes. 2. The milk stations should not be allowed to defeat their own purpose, which was that of the reduction of infant mortality by encouraging artificial feeding. The question of breast-feeding among the tenement population was largely an economic one. The mothers were often forced to go to work or were insufficiently nourished themselves to furnish proper nourishment for their babies. The milk stations should give milk to nursing mothers. Dr. Baker was opposed to the giving of premiums to nursing mothers. She thought the name "Infants' Milk Station" was an unfortunate one, and that a name should be devised which would call attention to the educational side of the work as well as to the distribution of milk. She approved of the home modification of milk and said it was the intention of the Health Department to furnish plain milk and to have the mothers instructed in the methods of modification for infant feeding.

Dr. Sidney V. Haas agreed with the conclusions of Dr. Hermann. Five years ago, while abroad, he looked up the question of milk stations. These had been started in Berlin about six months before, under the name of "Fürsorge-Stelle"; they had distributions of money premiums to nursing mothers, although in Paris, where the idea was first tried out at the "Consultations des Nourrisons," the money premiums had at that time already been abandoned because of the unfortunate experiences they had had with them. It was found that one woman, because of her small income, received 9 francs weekly, and another, because of a somewhat larger income, received only 5 francs; when the latter learned of this larger sum being received she threatened to discontinue breast-feeding unless her premium was raised. The work progressed more satisfactorily without premiums. The other organization in Paris at that time was the "Goutte de Lait," an organization comparable to one of our large milk companies, with numerous stores at which milk could be obtained either at the regular price by anyone or for half price or for nothing, tickets for the latter being obtained at the central office after careful examination and investigation which required renewal each month. This concern was able to pay a large dividend.

In regard to milk stations nothing could be worse than calling them by that name. The name implied that milk could be obtained there and that breast-feeding was not necessary. It seemed to Dr. Haas that they were going to add to the infant mortality and to create chaos instead of order. These depots might be made of great value if the babies could be supervised according to the methods outlined. In procuring physicians for this work they should get men trained by institutional work or other experience It was thought a few years ago that breast-feeding was fast becoming a lost art, but more recent experiences had shown that from 70 to 80 per cent. of the babies could be breast-fed. It was important to impress upon the mothers that the infants should be breast-fed. Dr. Haas said that the plan of having milk stations was an ideal one, but the name should be changed; the stations should be placed in the rooms of some organized institution and the milk supply should be at no cost to these institutions.

Dr. Charles Gilmore Kerley said that in his experience these women did not require much persuasion to continue nursing their children; they learned that it was best to nurse their babies. He believed that the milk stations were useless and might prove to be harmful unless supplied with adequate instruction. His eighteen years' experience with out-patients on the East Side impressed him with the fact

that not only did they need instruction, but they were willing to receive it.

Dr. Henry Koplik said that we were apt to make a mistake when we tried to carry out in America the work done in Europe. Reluctance on the part of the mother to nurse her child was a factor which in his experience in this country could be left out. He thought the milk depots had come to stay, but there should be a physician in attendance to instruct the mothers. These stations did much good in saving life. The only ones that did harm were those without proper control.

Dr. Godfrey R. Pisek agreed in the main with Dr. Hermann's conclusions, but did not agree as regarded the value of the consultations. There was no doubt as to the real value of these consultations. The mothers were given an opportunity to compare their infants with others, not only as regarded nutrition, but clothing and general development as well. They looked forward with interest to these weekly consultations. There was no doubt as to the value of the "follow up" system and the conferences that were held between mother and nurse. He had found that it was only the very exceptional mother who could not be taught how to modify milk at home. As to the distribution of pamphlets for the instruction of mothers it should be remembered that the personal equation counted far more than literature. The only way to reach these women was through doctors and nurses.

Dr. Thomas S. Southworth said that if as stated there were thousands and thousands of children that were being fed on the bottle because there was no breast milk this was the strongest argument in favor of sending out nurses into the homes to give advice about their feeding before they were entirely deprived of their breast milk. If the importance of breast-feeding were better taught so many of these children would not come to the milk dispensaries.

Dr. Edward B. Cragin said that the education of the public regarding the importance of breast-feeding had borne fruit and the majority of women were not opposed to nursing their babies. The percentage of those in the so-called higher walks of life who were unable to nurse after a few weeks was extremely large. This was one of the penalties of modern life. As many as 30 or 40 per cent. of such women were incapable of furnishing milk for their babies.

Dr. Charles Hermann, in closing the discussion, said that because of the birth certificates they could get information regarding these babies at the time of birth. Forty per cent. of the births in the greater city were in the charge of mid wives and their reports came to the Department of Health. He thought that there was no doubt but that the milk depots should be conducted with the affiliation of proper instruction on the part of visiting nurses.

Gastrointestinal Radiography a New Auxiliary in Legal Medicine.—Charles Vaillant says that we can control by radiography the earliest phases of infantile life, since we get different appearances according as the lungs have or have not been inflated at birth. Infants which have never lived at all show no visible organs; those which have inspired a few times show the stomach slightly; when the child has lived an hour the stomach is more transparent and the intestine becomes visible; when the child has been fed the lungs as well as the abdominal organs become visible, the liver is seen and then the heart comes into view. Infants which have been fed regularly show all the organs, and the gas in the intestine causes a more intense image of the intestines. In case of the death of a newborn child the lapse of time between birth and death is indicated by these radiographic appearances within certain limits. These appearances are of medicolegal value.—*Journal de Medecine de Paris.*

Diseases of the Lungs. By Sir. R. Douglas Powell, Bart., K.C.V.O., M.D. Lond., F.R.C.P., and P. Horton-Smith Hartley, M.V.O., M.A., M.D. Cantab., F.R.C.P. 712 pages; illustrated; cloth; price $6.00 net; P. Blakiston's Son & Co., Publishers.

Suggestive Therapeutics, Applied Hypnotism, Psychic Science. By Henry S. Munro, M.D. 409 pages; cloth; price $4.00 C. V. Mosby Co., St. Louis, Publishers.

Transactions of the Southern Surgical and Gynecological Association. Vol. XXIII, 23rd Session, held at Nashville, Tenn., December 13, 14 and 15, 1910. By W. D. Haggard, M.D. 532 pages; illustrated cloth. Published by Southern Surgical and Gynecological Association.

Handbuch der Speziellen Chirurgie des Ohres und der Oberen Luftwege. By Dr. H. Preysing and Dr. F. Blumenfeld. 240 pages; illustrated; paper; price 12 M. Curt Kabitzsch, Wurzburg, Publisher.

Heredity in the Light of Recent Research. By L. Doncaster, M.A.; 143 pages; illustrated; cloth. G. P. Putnam's Sons, Publishers, New York. Price $.40 net.

The Coming of Evolution. By John W. Judd, C.B., LL.D., F.R.S.; 171 pages; cloth; price $.40 net. G. P. Putnam's Sons, Publishers, New York.

A Comparison Between the Bordet gengou Fixation Reaction, and the Wassermann Reaction Based on the Relative Dosage of the Reacting Substances. By Frederick P. Gay. 28 pages. Published by University of California.

The Fixation Reaction in Relation to the Formation of Specific Serum Precipitates. By Frederick P. Gay. 22 pages. Published by University of California.

Diseases of the Stomach. By Charles D. Aaron, Sc.D., M.D. 555 pages; with 42 illustrations and 21 plates; cloth. Lea & Febiger, Publishers, Philadelphia and New York.

Thirty-fourth Annual Report of the Board of Health of the State of New Jersey, 1910, and Report of the Bureau of Vital Statistics. 607 pages; cloth.

Norsk Medicin. By S Laache. 289 pages; illustrated; paper. Steen'ske Boktrykkeri, Publishers, Kristiania.

Progressive Medicine. Vol. XIII, No. 3. By Hobart Amory Hare, M.D. and Leighton F. Appleman, M.D. 328 pages; illustrated; price $6.00 per annum. Lea & Febiger, Publishers, Philadelphia and New York.

On the Relation Between Rat and Human Leprosy By L. S. Schmitt. 73 pages; paper. Published by University of California.

Errors of Refraction Occurring in the Students of the University of California. By Theo. C. Burnett. Published by the University of California.

Some Factors Influencing the Quantitative Determination of Gliadin. By J. E. Greaves. Published by the University of California.

Collected Papers by the Staff of St. Mary's Hospital (Mayo Clinic) 1910. 633 pages; illustrated; cloth; price $5.50 net. W. B. Saunders Co., Philadelphia, Publishers.

A System of Medicine. Vol. IX. Diseases of the Skin By Sir Clifford Allbutt, K.C.B. and Humphrey Davy Rolleston, M.A., M.D. 869 pages; illustrated; cloth; price $6.00 net. The Macmillan Company, New York. Publishers.

A Text Book of the Practice of Medicine. The New (10th) Edition, Revised. By James M. Anders, M.D., Ph.D., LL.D., 1328 pages; illustrated; cloth; price $5.50 net, half Morocco $7.00 net. W. B. Saunders Company, Philadelphia, Publishers.

The Treatment of Fractures. The New (7th) Edition, Enlarged. By Chas. L. Scudder, M.D. 708 pages, with 990 illustrations. Price, Polished Buckram, $6.00 net; Half Morocco, $7.50 net. W. B. Saunders Company, Philadelphia, Publishers.

A Text Book of Physiology. The New (4th) Edition Revised. By Wm. H. Howell, Ph.D., M.D., LL.D. 1018 pages; illustrated; price, cloth $4.00 net, half Morocco $5.50 net. W. B. Saunders Company, Publishers, Philadelphia.

Malaria. Its Prevention and Control. By Graham E. Henson, M.D., E. Van Hood, M.D. and W. W. Warren, M.D. 43 pages; paper. Published by State Board of Health of Florida.

Medical Chemistry and Toxicology. The New (3d) Edition, Revised. By James W. Holland, M.D. 655 pages; illustrated; cloth; price $3.00 net. W. B. Saunders Co., Philadelphia, Publishers.

A Manual of the Practice of Medicine. The New (9th) Edition, Revised. By A. A. Stevens, A.M., M.D. 573 pages; illustrated; flexible leather; price $2.50 net. W. B. Saunders Company, Philadelphia, Publishers.

The American Pocket Medical Dictionary. The New (7th) Edition. By W. A. Newman Dorland, M.D. 610 pages; flexible leather $1.00 net; thumb indexed $1.25 net. W. B. Saunders Company, Philadelphia, Publishers.

Reference Handbook of Obstetric Nursing. Second Edition. By W. Reynolds Wilson, M.D. 256 pages; illustrated; flexible leather; price $1.25 net. W. B. Saunders Company, Philadelphia, Publishers.

Nursing in the Acute Infectious Fevers. Second Edition Revised. By George P. Paul, M.D. 246 pages; illustrated; cloth; price $1.00 net. W. B. Saunders Company, Philadelphia, Publishers.

The Conquest of the Nerves. By J. W. Courtney, M.D. 209 pages; cloth; price $1.25. The MacMillan Company, New York, Publishers.

Dorland's American Illustrated Medical Dictionary. The New (6th) Edition Revised. By W. A. Newman Dorland, M.D. 986 pages, with 323 illustrations. Price, flexible leather $4.50 net, indexed $5.00 net. W. B. Saunders Company, Philadelphia, Publishers.

Practical Pathology. By Aldred Scott Warthin, Ph.D., M.D. Second Edition. 310 pages with 55 figures; cloth. George Wahr, Ann Arbor, Publisher

Lehrbuch der Spezifischen Diagnostik und Therapie der Tuberkulose. By Dr. Bandelier and Dr. Roepke. 296 pages; illustrated; paper; price 6.60 M. Curt Kabitzsch, Wurzburg, Publisher.

Experimentelle Grundlagen der Chemotherapie der Spirochaeten-Krankheiten mit Besonderer Berucksichtigung der Syphilis. By Prof. Dr. Paul Uhlenhuth. 313 pages; paper, price 18 M. Urban & Schwarzenberg, Berlin, Publishers.

The Practical Medicine Series. Vol. VI. General Medicine. By Frank Billings, M.S., M.D., and J. H. Salisbury, A.M., M.D. 353 pages; cloth; price $1.50. The Year Book Publishers, Chicago, Publishers.

Principles of Anatomy. By Wm. Cuthbert Morton, M.A., M.D. 174 pages; illustrated; cloth; price $12.00. Rebman Co., New York, Publishers.

Refraction and Visual Acuity. By Kenneth Scott, M.D., C.M., F.R.C.S. 191 pages, with 16 illustrations and a colored plate; cloth; price $1.75. Rebman Company, New York, Publishers.

Cesare Lombroso. By Hans Kurella, M.D. 194 pages; cloth; price $1.50. Rebman Company, New York, Publishers.

Compendium of Regional Diagnosis in Affections of the Brain and Spinal Cord. By Robert Bing. 215 pages with 70 illustrations; cloth; price $2.50. Rebman Company, New York, Publishers.

The Mechanism of Life. By Dr. Stephane Leduc; 172 pages; illustrated; cloth; price $2.00. Rebman Company, New York, Publishers.

Love and Letters. By Frederick Rowland Marvin. 252 pages, cloth; price $1.50 net. Sherman, French & Company, Boston, Publishers.

Experimental Transmission of Leprosy.—Rodolfo Stanziale has injected into animals fresh material obtained from two cases of anesthetic leprosy, aspirated from cutaneous tubercles and consisting of a leprous fluice. Two series of experiments were made on thirty-one rabbits in all. After the reports on his work had been made by the author to the commission appointed by the Academy of Medicine this body endorsed his work. The commission found that the author has established the experimental transmission of leprosy from man to animals. He exhibited preparations derived from intraocular experiments, rich in lapra bacilli, which by their large number, by the structure of the cornea and the topographical position of the germs in the anterior chamber of the eye, as pure granulomatous formations on the iris, leave no doubt that these lapra bacilli were generated in this position by proliferation, and not simply by disaggregation of the injected bacilli. Small tumors were formed at the place of inoculation and in the iris which were rich in lepra bacilli.—*Giornale Internazionale delle Scienze Mediche.*

SPECIALISM IN MEDICINE.*

By EDWIN B. CRAGIN, M.D.,

NEW YORK.

THE type of medical man which most appeals to the writers both of poetry and prose is that of Dr. William MacLure, in "Beside the Bonnie Brier Bush," who through summer and winter on his old mare Jess rode up and down the glen of Drumtochty, ministering to the needs of the common folk and their bairns. MacLaren says of him: "He was chest doctor and doctor for every other organ as well; he was accoucheur and surgeon; he was oculist and aurist; he was dentist and chloroformist, besides being chemist and druggist." Yet even MacLure, when Tammas Mitchell's wife Annie lay desperately ill, knew that only he could save her who had spent his life in a special line of training, and the story of how he brought Sir George through the Tochty flood to the bedside of Annie and how Sir George by successful operation saved her life has touched the hearts of thousands.

Specialism in medicine is characteristic of the times, and specialism has come to stay. No one working along a special line can meet in consultation the good all round man of the country who has to meet the demand for anything in medicine or surgery and run the gamut of all the specialties between, without being impressed with the breadth and manysidedness of the general practitioner of the country. Truly it may be said of him as Sir George said of MacLure, "He is an honor to our profession." However, the science of medicine today is too extensive for any one man to compass it. The literature of any one specialty is almost beyond the grasp of the individual. Limitation is a necessity for thorough work, and thorough work is successful work.

It must not be thought that specialism as it is found in medicine is unique or unusual. The same tendency to specialize is seen in the arts and trades. In the erection of the new gynecological building of the Sloane Hospital I was interested in noting the number of special workers employed, and was somewhat surprised to find that from the turning of the first sod in the excavation till the building was ready for the first operation thirty special classes of workmen had been employed, each working in an individual field, each trained to do a special kind of work and no other. Certainly specialism is not confined to medicine, nor would the sum of human knowledge be what it is to-day had it not been for special workers delving deep into the wells of technical knowledge whose secrets are hidden from all save those who search day in and day out along a special lead.

Granted that there are certain definite advantages in the special study of one branch of medicine and that long focusing of attention and effort upon the science, diagnosis and technique in one line of work brings crystallized results, the question naturally arises, What are the disadvantages? That such exist is known to every one, and it is only by recognizing them and warding against them that the best type of special workers is developed. In the first place the specialist is naturally a narrow man. The aurist who day after day spends his time confining his vision to the limits of his tubular speculum, even if in modern times he has extended his field to the throat, the mastoid and the lateral sinus, naturally has a narrow field of work, and unless he is careful his thoughts by day and his dreams by night are on ears, ears, ears, and other organs of the body fade away in the distance. In the same way the ophthalmologist whose life work has been limited to the technical knowledge and treatment of diseases of the eye naturally narrows his view and is inclined to think of the body in terms of the eye. What has been said of the aurist and ophthalmologist may be said with equal force of the laryngologist, the proctologist, the gynecologist and the other specialists.

Many a man has so centered his study, his thought, his practice and his interest in one organ as practically to forget, that this is only one of many organs in the body more or less interdependent and each demanding consideration. The result in technical knowledge of the different organs as derived from specialism has been great, but the natural effect upon the special worker is narrowing. Unless the specialist is careful he becomes nothing but a tool in the hands of the general medical adviser, whose vision is broad enough to study the human body as a whole, and to select from the collection of tools at his command, the proper one for the cure of his patient. The disadvantages and evils of specialism have been laid before you. The problem now is how can these be overcome?

In the first place do not specialize too early. One of the common tendencies among young medical students and even prospective medical students, is to have a fixed idea that they are to be specialists in medicine, and that a certain specialty is to be the field of their life work. If a personal allusion may be pardoned, the speaker remembers distinctly, prior to his first year in the medical school, writing to a well-known ophthalmologist of his native State, saying that he expected to make the eye his life work and asking his advice as to the best course to pursue. My learned friend wisely advised me to postpone my decision as to a specialty until I had finished my college and hospital course. The years have rolled by and those who are familiar with the

*Opening Address to the Students of the College of Physicians and Surgeons, Medical Department of Columbia University, September 28, 1911.

field of my life work would hardly consider that I had been true to my first love. In fact, if my colleague in the chair of ophthalmology were to express an honest opinion, it would probably be that the only disease of the eye the speaker was fitted to treat was ophthalmia neonatorum and even of this he might have grave doubt.

As medical students we know little of what line of work will especially attract us. We know little of what work we are best fitted for, and still less in what work our best opportunities will present themselves. If you were to ask the best preparation for a good specialist I should say, develop yourself first as a man, second as a doctor, third as a specialist. Whatever the field of your choice, it is first the man which counts. One writer has said, "What you are speaks so loud I cannot hear what you say," and this holds good in medicine. That there are apparent exceptions to the rule that the true man in medicine is the one who deserves and wins success may be granted for a time, and in small towns you will occasionally hear it said, "I would rather have A drunk than B sober," but such a result is short lived and exceptional. It is the man of strict integrity, sterling character and broad sympathies who alone has the right foundation for the successful general practitioner or specialist. If it is important that the general practitioner should have a broad general education before beginning the study of medicine, it is still more important for the specialist, as the former has not to cope with the narrowing tendencies which handicap the latter.

We have spoken of the need of a broad general education for the specialist before beginning the study of medicine. This need for a broad general education applies with even greater force in medicine itself. I feel that I am safe in saying that the one great regret in the mind of every specialist in active practice is that he did not have a broader medical training before limiting his field of experience. Oh, if he knew more pathology! If he only felt more certain of the exact condition of that heart! Does that eruption mean scarlet fever or German measles? These are echoes from the mind of more than one specialist whose field of work has been more or less foreign to these suggestions. To say that the medical training of the specialist should be like a pyramid with broad foundation rising from the plain and tapering to its apex as he limits his field of work would be trite, almost a platitude. Nay, rather would I compare the specialties in medicine to the presidential range of the White Mountains, viewed from a distance. The lower portion of the range belongs to them all in common, and it is only as you approach the summits that you see Washington, Adams, Jefferson, etc., standing out in the sky line. So it should be with the specialties in medicine, their foundations interwoven and formed in common and only on the broad foundation of general medical knowledge should the true specialiasts project in the sky line, here ophthalmology, and there otology, and the other specialties.

The time may come in the life of any one of you when the limitation of your field of work is either necessary or distinctly desirable. What will be your choice? This should depend largely upon two conditions. 1. Your opportunity for work. 2. Your natural taste and fitness for the work. Probably the first question which presents itself to every would-be specialist is what branch of the profession offers me the greatest opportunity? If you are an army surgeon and expect to perfect yourself as an army surgeon there will be very little sense in your specializing in Gynecology. It is only rational to select that line of work of which there is much to be done, and preferably much done in hospitals, for here it is that the necessary training and experience must be obtained. The question of opportunity naturally resolves itself into this: In what line of work have you hospital opportunities, or after years of dispensary service are you likely to have hospital opportunities? You may have thought and dreamed for years of student life that a certain line of work would be your specialty. Yet suddenly your opportunities in that direction may be closed and the doors open in another. In general, the guiding hand to the individual specialty in a large city is that of opportunity, and foolish is the man who does not consider it. The next question which presents itself is that of taste and fitness. Of several specialties presenting opportunities, which appeals most to your natural taste and for which are you best fitted? Although closely related and interdependent there appear to the speaker to be three classes of specialties. (1) The laboratory specialty, in which, secluded from the beck and call of the public, the special worker can pursue uninterruptedly the solution of the problem which is to bring fame to himself and perhaps lasting benefit to the world. (2) The surgical specialty, in which a surgical training and fondness for surgery are a prerequisite. (3) The non-surgical specialty.

The first division comes along the line of practice, or no practice. One man has no taste for dealing with people, his interest in the patient only begins as life departs. He is perfectly happy in the autopsy room and in his laboratory, with his test tubes, his microscope and various instruments of precision. The other man cares little for the seclusion of the laboratory, but is fond of dealing with people; of studying their individual needs and relieving them. Nothing gives him so much happiness as to keep from the pathologist him or her whose life he has spent anxious days and nights in trying to save.

The second division falls along the line of surgery or no surgery. Some men have no liking for surgery, or are by nature incapacitated for it. On the other hand, the definiteness of results and the speedy attainment of results from surgery appeal to some men as nothing else would. Now, while nearly every specialty is intimately connected with surgery and requires surgery in some of its lines of treatment, the different specialties vary greatly in this respect. In some the work is practically all surgical and must be done by the specialist himself, while in others, the need for surgery is only occasional and can easily be referred to the general surgeon for its performance. In fact, it is better so referred as the need for surgery in the specialty of this class is so infrequent as to be insufficient for the maintenance of the proper technique and practice on the part of the operator. Now, for a man to select, in deciding upon his special life work, a specialty in which the work is chiefly surgical, when he both by taste and by training is unfitted for surgery is most unwise, and the more so as there are other specialties in which surgery enters very little, and in those instances can easily be delegated.

It will be noticed that in discussing the two conditions; opportunity and taste, in the choice of a

specialty I placed opportunity first and taste second, and this I did advisedly, feeling that the taste for a line of work is often a changeable quantity and is often dependent upon opportunity. Well do I remember the time when the present occupant of the chair of anatomy in this university, now known far and wide as an authority on his subject and absolutely devoted to it, was a skilled and most enthusiastic surgeon, looking forward to surgery as a life work, yet there came in his path a parting of the ways with the choice between anatomy and surgery as his career. From its opportunity for greater usefulness, anatomy woed and won him, and the two have been happily united ever since, and I venture to add without a regret over his choice.

Having decided upon your specialty and having laid your foundation broad, both in general education and in general medicine, both theoretical and practical, the question naturally presents itself: How can I prepare myself for my individual specialty?

With a view to answering this question authoritatively for you, I wrote to the heads of several of the special departments of this faculty, inquiring their opinion as to the best preparation for their specialty. With their permission the following is abstracted from their replies:

From Professor Starr, Department of Neurology.—"For preparation in neurology the first requisite is a thorough knowledge of the histology of the nervous system. This requires eight hours' work a day in a laboratory for three months, to be followed by a similar time in a laboratory on the pathology of nervous diseases. The best laboratories offering these courses are Obersteiner's in Vienna; Oppenheim's in Berlin and Dejerine's in Paris, or Spiller's in Philadelphia. After this preliminary work a year should be spent in clinical work in dispensaries and in hospitals. In Vienna, Berlin and Paris such courses are offered. Work in London is limited to two hours daily in the Hospital of Epileptics and Paralytics, but on the continent six hours daily can be done. During this year of clinical work three months should be given to psychiatry in a hospital. This is best obtained with Ziehen in Berlin, or with Kraepelin in Munich. The only way of obtaining instruction in psychiatry in America is to obtain a place as interne in an asylum, and there the routine duty precludes systematic study. There are at present no adequate hospital courses in neurology offered in America as no such special wards exist in the hospitals."

From Professor Bacon, Department of Otology.—"For the best preparation for an aurist a man should first obtain a degree in Arts or Science. After leaving the medical school he should have the best training he can get in a general hospital, particularly in surgery. He ought to have a medical service as well, so that he can look at his patient in a broad way and not jump at the conclusion at once that if a patient has tinnitus aurium, local treatment of the ear will cure the difficulty. It would be a good thing if he could have several years of general practice before taking up otology. He should then become an interne at an eye and ear hospital and serve through the different grades. In a hospital like the New York Eye and Ear Infirmary, where there are performed each year between six and seven hundred mastoid operations and many operations for intracranial complications, a man can obtain an immense experience in a very short time and learn at the same time from many teachers. The internes who have followed such a course have acquitted themselves well after leaving the hospital, and are a credit to the institution."

From Professor Knapp, Department of Ophthalmology.—"For the best course to be pursued by one desiring to become an ophthalmic surgeon I would advise by all means a general hospital service in which both medicine and surgery are combined. If this is not possible I think a surgical service would be of greater value than a medical one. I would then advise a year's service in a special eye hospital, and after that, if possible, to study for a further year in European eye clinics and hospitals with particular attention to nervous diseases and general pathology."

From Professor Jackson, Department of Dermatology.—"Dermatology of all the specialties is most a part of general medicine. A great number of the diseases of the skin are due to disorders of the internal organs, of nutrition and of the nervous system. The better a general practitioner a man is, the better dermatologist he will make. Therefore, the best preparation for a dermatologist is a thorough training in general medicine, including hospital experience. A young man should serve for years under older and more experienced men. Dermatology can not be learned from books alone. Any man who has not spent years in handling cases and subjecting himself to the constant criticism of other experts should not esteem himself a competent specialist."

From Professor Simpson, Department of Laryngology.—"In preparation for a laryngologist a man should have a good general surgical training, for surgery enters so very largely into laryngology and rhinology that it becomes absolutely necessary to be well grounded in surgical principles and technique. This would permit him to meet all the requirements of the specialty when the aid of surgery was to be invoked. It is sometimes the case that a patient is turned over to a general surgeon, who, though having a better knowledge of surgery, has not the proper regional or functional knowledge for the best treatment of the case. The laryngologist should combine both of these requirements. He must be a good surgeon. After a hospital internship he should connect himself with a good laryngological dispensary service, preferably one in which there is a hospital bed service, so that he can properly follow his operative cases. In addition to a laryngological dispensary service he should follow general practice for some years before devoting his entire time to laryngology. This could be done either by association with a medical clinic, or by general bedside practice. This aids greatly in preventing a specialist from becoming a man of one idea, and permits him to place his cases in their proper relation. A laryngologist should also have a good training in pathology and bacteriology. Deftness, gentleness and patience in instrumental manipulation should be an absolute requirement in laryngology. This may be partly inherent in the individual, but is generally the result of long practice and experience. Study in foreign clinics, though perhaps not absolutely necessary, is undoubtedly of great value. Of equal value also is an acquaintance with the methods and ideas of those prominent at home."

Department of Obstetrics and Gynecology.—In these departments, over which the speaker has the honor to preside, there can be no question that a

broad general training, and especially a thorough surgical training, is of the utmost importance. For preparation as a specialist in obstetrics, thanks to the donors of the Sloane Hospital for Women, it is no longer necessary for students and graduates of Columbia University, if of high rank, to pursue their study of this branch abroad. In no place in the world is a better preparation obtainable than that gained by taking after graduation from a general hospital, especially one with a surgical service, a three months' service at the Sloane Hospital, spending one month in each of the three grades of Junior Assistant, Day Senior Assistant, and Night Senior Assistant Obstetrician, and then crowning this experience by an appointment for two, or, better, for three years as Resident Obstetrician to the Sloane Hospital with the title of Instructor in Obstetrics in Columbia University. While this appointment is made at the earliest only once in two years, it is a reward possible to those of marked fitness for the work, and who are anxious to specialize along this line. As regards the specialty of gynecology I am forced to admit that at present Vienna, with its wealth of material and its unique control of the same, offers a greater field in gynecological diagnosis than is easily attainable in this country, but there is developing at the Sloane Hospital in connection with the Vanderbilt Clinic a Department of Gynecology, in which a man after a broad general surgical training can spend two years in the position of Resident Gynecologist, and obtain ere long a preparation in the specialty of gynecology second to none in the country, and it is hoped in the world.

Nothing has been said thus far of what might be called the specialty of the general medical consultant, the head of the clearing house of the different specialties, a specialty possible only in large towns or cities, and a specialty perhaps the least crowded of any. This represents a field of work open only to those of large medical experience in hospital wards and usually in teaching chairs; the crowning reward of the medical man with broad training, wide experience and the universal respect of the community, both lay and medical, in which he lives.

Gentlemen, I have tried to present to you the highest types of specialism in our chosen profession. Low ideals and insufficient preparation bring neither satisfaction nor permanent rewards, but if after a thorough college and hospital training you decide to limit your field of work and will each aim at high ideals as a man, as a doctor, and as a specialist, success will deservedly be yours.

RESULTS IN TWO CASES TREATED BY VACCINE THERAPY.

By C. L. McDONALD, M.D.,

CLEVELAND.

BACTERIOLOGIST TO ST. ALEXIS HOSPITAL.

My reason for reporting these cases is that they represent a type of chronic infection very amenable to bacterial therapy. It might be well to mention that such infections as occasionally follow amputation, scalp injury, etc., are equally responsive to this form of therapy. The following cases were both due to infection by the *Staphylococcus albus* and were treated by stock vaccines prepared in my laboratory.

Mr. R., while handling lumber, drove a splinter into the palm of his hand. Three days later the hand became greatly swollen and very painful. The next day it was opened in several places and a large quantity of pus evacuated. The patient was then instructed to soak his hand in hot bichloride solu-

Fig. 1.—Case I, before inoculations were begun; the dressing shows the amount of discharge in twenty-four hours.

tion one hour three times a day and return every day for dressing. At the end of two weeks the discharge had greatly decreased but the swelling persisted. Eight weeks later with the hand still much swollen and discharging the amounts seen on the first photgraph he was referred to me for vaccine treatment. A smear and culture showed the causative organism to be a *Staphylococcus albus*. The patient was inoculated with a stock vaccine prepared from a similar case, the initial dose being 150,000,000 dead staphylococci. He returned seven days later with the swelling and discharge greatly lessened. A second inoculation of 200,000,000 was given, followed by further improvement. On the fourteenth day a third inoculation of 300,000,000 dead staphylococci was given and on the twenty-fifth day the discharge and swelling, as shown on the second photograph, had entirely disappeared.

The next case is of special interest in that vac-

Fig. 2.—Case I, after three inoculations had been given.

cines were not used until the usual medical and surgical measures had ceased to benefit the patient. Mrs. B., twenty-five years old, had a severe postpartum hemorrhage at the birth of her last child. The physician in charge gave a physiological

saline infusion under the breast. About two weeks later an abscess appeared at the site of operation, which was opened and packed in the usual way. At the end of six weeks, owing to a continuous discharge, the breast was again opened, curetted, and

Fig. 3.—Case II, before inoculations were begun, the dressing shows the amount of discharge in twenty-four hours.

packed, which brought about considerable improvement but at no time did the discharge subside completely. A third operation two months later, similar to the second, followed by daily irrigation by saline solution, brought about no further improvement. Six months after her last operation, with her breast discharging about 2 drams of pus a day, she was referred to me for therapeutic immuni-

Fig. 4.—Case II, after two inoculations had been given.

zation. Smears and cultures showed the causative organism to be a *Staphylococcus albus*. The patient was inoculated with 150,000,000 dead staphylococci, which was followed by slight soreness at the site of the inoculation and slight increase of the discharge from the breast for the following two days. On the fourth day the discharge was considerably lessened, and became more watery. On the seventh day she was given a second inoculation of 200,000,000 dead staphylococci, and this was followed by a disappearance of the pain, which had been continuous since the beginning of the infection. On the fourteenth day, with the discharge and pain absent, she was given a third inoculation to prevent a recurrence. Six months have elapsed since her last inoculation and her breast has remained well.

TONSIL REMOVAL WITH SPECIAL REFERENCE TO QUININE ANESTHESIA.

By BRYAN D. SHEEDY, M.D.,

NEW YORK.

ADJUNCT PROFESSOR RHINOLOGY AND LARYNGOLOGY, FORDHAM UNIVERSITY MEDICAL COLLEGE; INSTRUCTOR DISEASES NOSE AND THROAT, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; CONSULTING OTOLOGIST, RHINOLOGIST, AND LARYNOLOGIST, ST. JOSEPH'S HOSPITAL.

The technique connected with tonsillar enucleation cannot be properly understood and appreciated without a proper and definite understanding of the anatomy and physiology of the faucial tonsil. In this article tonsillectomy and tonsillar enucleation will be considered synonymous terms, the term tonsillotomy being used only when referring to the old operation where a portion of the tonsil was removed by the tonsillotome, snare, scissors, or punch. The newer operation aims to remove all of the gland with its capsule, while the operation that has been practised for years aimed to remove only a portion of the hypertrophied tissue. To appreciate this subject properly, it is necessary for us to refresh our memory in regard to the arrangement of lymphoid tissue surrounding the upper opening into the body. This ring of lymphoid tissue bears the name of the great anatomist, Waldeyer, who first presented a description of it to the medical profession.

The lymphoid tissue, located in the various recesses of the nasopharyngeal space, is generally described as tonsils. The more prominent being: (1) The faucial tonsils, (2) the pharyngeal tonsil, (3) the lingual tonsil.

The glandular tissue distributed in and around the larynx in more or less irregular outline I shall not designate as a tonsil though many laryngologists speak of the arrangement as the laryngeal tonsil. It is necessary in connection with this description to remember that there are such masses and that these masses frequently ulcerate in typhoid and other pathological conditions.

The faucial tonsils are two masses of lymphoid tissue symmetrically located between the anterior and posterior pillars of the fauces. Their free surface opens into the oropharynx while externally they rest on cellular tissue, which in turn rests on the pharyngeal aponeurosis. External to the aponeurosis we have the superior constrictor of the pharynx with the sheath of the external carotid artery. Pulsations from this artery are readily felt through the tonsil when the same is enlarged. Above the tonsil is a triangular space generally spoken of as the supratonsillar space. Below the tonsil is a deep sulcus separating the tonsil from the tongue. This depression is often filled with lymphoid tissue so that the faucial and lingual tonsils appear as one mass.

In the days of tonsillotomy, when the assistant

forced in the tonsil from without, it was important to press the side of the neck corresponding to the interval between the angle of the lower jaw, the anterior border of the sternocleidomastoid muscle, and the tip of the great cornu of the hyoid bone. This is also the space in which we make our incision when approaching the tonsil from without.

The close proximity of the carotids, as well as the ascending pharyngeal and the ascending palatine vessels, should be uppermost in the mind of the operator where the newer operation is being performed. At the present time there seems to be little difference of opinion among men best qualified to judge that, if the tonsil is in such condition as to require operative procedure, the whole of the diseased organ should be removed. At the beginning of the Christian era the teaching of the profession seems to have been that "tonsils which remain indurated after inflammation should be loosened and torn out and if this cannot be done they should be seized by a hook and excised." I presume that the large number of hemorrhages following this procedure caused another writer about five hundred years later to advise that "only one-half of the gland or the projecting portion be removed." With the perfection of the microscope and the acceptance by the medical profession during the past few years that the tonsil is an acknowledged gateway for such diseases as rheumatism, tuberculosis, and many other infectious conditions, there can be little doubt in the minds of the profession that if we are to operate at all we should remove the whole of the diseased organ, thus bringing about a complete cure. In other words, this gateway should be completely removed and the entrance closed to infectious material.

Almost every practitioner is daily called upon to care for patients suffering from tonsillar hypertrophy and symptoms associated with disease of these glands. Common conditions found in these patients are: (1) Chronic tonsillitis; (2) Peritonsillar abscesses due to infection of the small crypts in the peritonsillar tissues through enlargement of the tonsillar tissue and the interference of proper drainage; (3) Enlarged tonsils with crypts constantly containing tubercle bacilli and other infectious material; (4) Chronic pharyngitis due to the enlarged tonsil; (5) Ear conditions due to interference with proper aeration of the middle ear; (6) Enlarged glands in the neck due to the escape of infectious material from the tonsils into the lymphoid channels; (7) Laryngeal and lung conditions in children, due to mouth breathing on account of enlarged lymphoid ring; (8) Anemia due to the mouth breathing caused by nasal obstruction; (9) The below-par condition of all these patients due to lack of oxygen on account of mouth breathing; (10) Blood conditions such as rheumatism and heart diseases due to absorption of infectious material from decomposing matter found in the lacunæ of the enlarged tonsils.

There is little question but that many of the neuralgic conditions of the face and head are due to pressure by these large masses and there is no doubt in the minds of those who are daily caring for patients suffering from enlarged tonsils that the above symptoms and findings disappear and are permanently cured where the whole of the diseased mass is removed. While I believe tonsillectomy is the operation that should be performed in adults suffering from symptoms due to hypertrophied tonsils, I, at the same time, desire to impress upon the reader its dangers and contraindications. The operation is one that should not be done in the office or dispensary. A great many cases of death following the operation, due to one cause or another, have been recorded. The operation should be done in a hospital with all the surroundings that contribute to success in the event that unforeseen conditions arise. A few years ago all tonsils were removed under ether or chloroform anesthesia, and in children under ten years of age I believe that ether should be given in preference to any other anesthetic to-day. Following the introduction of cocaine and adrenalin many men injected these solutions into the tissues surrounding the tonsil. The large number of deaths reported have caused a number to discontinue the use of the cocaine and adrenalin mixture.

At the meeting of the laryngological section of the American Medical Association at St. Louis in 1910 I reported the following:

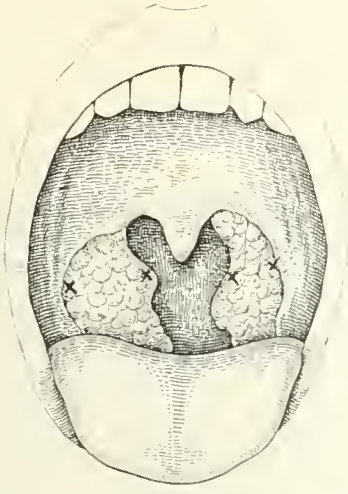
Case I.—(Before reported by T. I. H.). Man, aged thirty, in apparently good health, was given 1/60 of a grain of strychnine sulphate by the mouth. In about half an hour 2 drams of 1/5 of 1 per cent. cocaine hydrochlorate solution, containing adrenalin chloride were injected into the tonsils. This was followed in a few minutes by another injection, in all amounting to about 1/12 of a grain of cocaine and from 8 to 10 minims of a 1 to 1,000 adrenalin solution. Immediately after the second injection he complained of feeling ill, had a slight convulsion and turned ashy pale with profuse perspiration. His head was supported by an assistant and both tonsils were removed with the patient in an upright position. No hemorrhage followed the operation. The appearance of the patient following the operation, which did not require more than two or three minutes, was that of marked prostration and shock. He was therefore placed in the recumbent position, restoratives administered, and artificial respiration employed, but without result. Autopsy: Muscle wall of heart normal. Right auricle swollen and full of blood. All important organs of body apparently normal. Thymus enlarged.

Case II.—Man, aged twenty-five, in good health, except for an indisposition due to a slight attack of tonsillitis. About 1 dram of a solution made up of 1 grain of cocaine hydrochlorate and 1 dram adrenalin chloride 1 to 1,000 solution to 2 ounces of normal salt solution was injected in and around each tonsil. The patient almost immediately became faint, broke into a profuse perspiration, became very pale; as he complained that he was about to faint he was placed in a reclining position, restoratives applied, and after a few minutes he was put in an upright position and both tonsils removed. No hemorrhage followed the operation. As he seemed to be in a profound shock, he was kept in a room adjoining the operating room for more than an hour. He then started for home and fell in the street about a block away, and before assistance arrived he was dead. Autopsy: Slight extravasation of blood around tonsil region. All important organs apparently normal. No glandular enlargement.

Case III.—Man, aged forty-four, always enjoyed good health except for an attack of kidney trouble following scarlet fever when a boy. He called on his physician for removal of a large tonsil which had been giving some trouble. About 1 dram of a solution of cocaine hydrochlorate, 1

grain to the ounce, with from 7 to 10 minims of a 1 to 1,000 adrenalin chloride solution, was injected in and around the tonsil. As a part of the solution seemed to escape, in about fifteen minutes the injection was renewed. In less than three minutes' time after the second injection the patient became deathly pale, with no pulse at the wrist, and respiration became slow and labored, but improved slightly under a hypodermic of sulphate of strychnine, 1/30 grain. The head was supported by an assistant and the tonsil enucleated. The patient complained of marked weakness and prostration and was placed on a sofa, but before the surgeon could realize it there was no heart beat. All the ordinary restoratives were applied but without success. No autopsy.

Case IV.—Young man, aged between twenty-five and thirty, had always enjoyed good health except for a slight nervousness, which was attributed to overwork. The physician making the report writes as follows: "The patient had a deviated septum, with enlargement of the faucial tonsils, but otherwise was in perfect health, so far as we knew." Primary anesthesia was induced by a mixture of 3 parts of ether and 2 of chloroform. About 15



Cut showing pillars and tonsil and point for needle introduction. X X Points at which needle should be introduced.

minims of a 1 to 1,000 adrenalin chloride solution was injected, the amount being divided into 3 insertions of the hypodermic needle. In half a minute after the last injection the patient's skin blanched as white as skin could, the respirations deepened and slowed down until they finally ceased. In one minute after the patient became deathly pale he was dead. All the ordinarily employed restoratives were used with no apparent effect. No autopsy. The physician making the above report further remarks: "I am surprised at the apparent indifference of laryngologists to syncope and collapse following operations on the nose and throat, in which cocaine and adrenalin solutions have been used."

I enumerate these four cases merely to emphasize the fact that cocaine and adrenalin solutions can not be injected into the soft tissues surrounding the tonsils without grave danger, and mention these cases as a warning, and would suggest that in all cases in which local anesthesia is desired the application of cocaine be limited to the surface and not injected.

The many partial poisonings and the large number of prostrations in connection with the use of cocaine and adrenalin led me to look around for something to take the place of these poisonous and dangerous drugs. Water has been used for local anesthesia in other parts of the body with much success for a great many years. Quinine solutions in connection with urea have been tried but the anesthetic effect was not uniform and there was considerable sloughing following their use and a very great increase in the amount of post-operation pain. My first cases were operated upon after injecting sterile water, but this was not satisfactory as most of the patients complained of pain. I then used a 5 per cent. solution of quinine bisulphate. While there has been what appeared to be an increase of hemorrhage over the cases in which quinine was not used, I can report the complete absence of pain in all cases in which the solution was deposited outside the capsule of the tonsil and into the cellular tissue forming its bed. The solution should be introduced by an ordinary one-ounce piston syringe to which a long curved needle is attached, the point of the needle being forced through the mucous membrane between the pillars and the capsule of the gland at the point indicated in the illustration. About ½ drachm should be introduced inside the border of the anterior pillar and about the same amount at a point opposite between the capsule and the posterior pillar. The enucleation may begin as soon as the solution is injected, there being no occasion to wait as when cocaine is used.

There is no necessity to prepare the patient as for an ether operation. In fact, I believe that the patient can stand the shock of the operation much better if it is done following a meat meal. This is particularly so in cocaine operations. If the patient, however, is oversensitive in and around the fauces, it may be advisable to operate on an empty stomach rather than have the stomach contents ejected during the operation.

In adults the patient should be seated in a rhinological chair so that the head will be properly supported. As there is no pain associated with the work, it is not necessary for an assistant even to hold the head. As a rule the tongue will keep out of the way after the tenaculum is applied to the tonsil. A description given by Dr. O. A. Lothrop of Boston, Mass., of the manner in which he removes the tonsil seems to me almost complete and I, therefore, use it here:

"The gag should be inserted and steadied by the assistant. If necessary hold the tongue down with the depressor and with a small pledget of gauze on a holder sweep or wipe the pharynx dry. By so doing a clearer view is obtained and the blood does not spread so rapidly. With a curved tonsil tenaculum seize the tonsil in a firm grip, inserting one claw in the supratonsillar fossa and the other just on the under side. Catch the tonsil a little anterior to its center. This one grasp, if properly placed and locked, should be sufficient for the complete enucleation. Depress the base of the tongue on the side from which the tonsil is to be removed and the fold of the anterior pillar will become prominent. The assistant should now steady the tongue depressor as above suggested, while the tonsil is drawn inward by means of the tenaculum. Insert the edge of a small, very sharp scalpel under the tonsil and incise carefully through the mucous membrane and plica down to the capsule. The mucous membrane is very thin, and as soon as divided, there being traction on the tonsil, will retract and the shining

white capsule appear. Do not cut through the capsule, for the proper line of cleavage will then be difficult to find. There will be much more bleeding if the tonsillar tissue is cut. Continue incising cautiously through the mucous membrane along the inner edge of the anterior pillar until the supratonsillar fossa is reached. Do not insert the knife up under the pillars. With a blunt dissector push back the mucous membrane and anterior pillar, thus exposing a band of capsule, one-quarter inch wide, extending from the under surface of the tonsil to the supratonsillar fossa. There should be little or no bleeding if only mucous membrane has been incised. Any blood that may appear should be wiped away, for a clear view is essential. Traction should be made on the tonsil and the handle of the tenaculum should swing to the corner of the mouth on that side. The patient's head should be turned to that side and the other corner of the mouth retracted by the etherizer. Take the scalpel in the left hand if the left tonsil is to be removed first, and with the edge uppermost incise the reflected mucous membrane from the posterior pillar close to the tonsil, upward to the supratonsillar fossa, and then across its floor or apex to meet the anterior incision. By cutting up no blood from above can obscure the mucous membrane to be severed. Push back the mucous membrane and posterior pillar with the dissector and expose the capsule to the supratonsillar fossa. Any hemorrhage should be sponged away, as it is very important that the field be not obscured. The capsule has now been exposed and partial dissection has been begun on the complete periphery of the tonsil beyond its equator. Slip a wire snare loop over the handle of the tenaculum and down to the tonsil, but do not release traction of the latter. Place the loop between the capsule and the posterior pillar, being careful not to include the uvula. Bring the cannula of the snare down to the edge of the anterior pillar, but do not let the part of the loop first placed change its position. When the loop is tight set the screw on the snare and cease traction on the tenaculum, but do not remove it. The snare should now be screwed up very slowly, allowing three to five minutes in adults.

"The snare takes the plane of least resistance and thus completes the shelling out of the capsule from its bed. The only structures which it cuts are a little areolar tissue and the vessels entering in the lower part. If the line of cleavage has not been started the wire may cut through the tonsil tissue. It is possible, however, to remove a tonsil with its capsule intact without a preliminary incision. This is done by forcibly drawing the tonsil into the mouth and thus inverting the capsule. By this method the snare severs the mucous membrane and it may draw in with the mucous membrane portions of the pillars and thus do harm. For this reason the mucous membrane over the whole circumference should be incised first. By freeing the anterior pillar first the tonsil can be drawn inward and forward over the anterior pillar, thus giving better access to the posterior pillar. The writer has seen cases in which a nasal voice has followed because of laceration of the posterior pillar, which was drawn in by the unsevered mucous membrane. There is less hemorrhage in this method than in any other, for the cleavage plane of the capsule is the least vascular. Injury to the pillars and other tissues may cause considerable bleeding."

I would amend the above description by advising that a blunt-pointed tonsil knife be used after the first incision through the mucous membrane has been made.

If the patient is too young to have the operation done without ether the above description may be followed by placing the patient in the upright position and maintained in range of the light by the assistant, who should make it his business to see that the mouth-gag is properly adjusted and the head kept in the desired location.

The statement made by many writers that there is not as much hemorrhage after a tonsillectomy as after a tonsillotomy does not agree with my experience. I would, therefore, urge that all tonsillectomies be done in a hospital with proper assistance; that in children the operation be done with ether anesthesia, and that in adults bisulphate of quinine anesthesia be employed for the reason that up to date we know of no disadvantages, while at the same time it has all the advantages of the dangerous cocaine solutions.

164 West Seventy-third Street.

A PRELIMINARY REPORT OF A METHOD OF TREATMENT OF EMPYEMA IN YOUNG CHILDREN.

By JAMES H. KENYON, M.D.,
NEW YORK,
ASSISTANT SURGEON, BABIES' HOSPITAL.

The following method of treatment of empyema in young children has given such good results during the past year at the Babies' Hospital that this brief

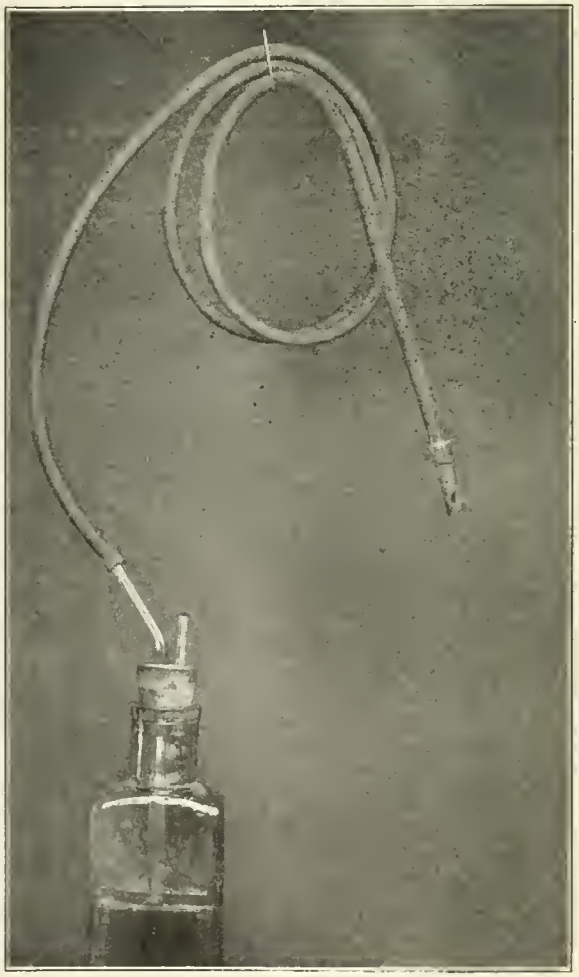


Fig. 1.—Tube with window, cuff, and tape; bottle with long and short glass tubes, half filled with salt solution; the long tube is always below the level of the fluid.

preliminary report of its important features seems warranted.

The pus having been located with the aspirating needle, a narrow-bladed knife is inserted into the pleural cavity along the lower side of the needle, which is left in place as a guide. This punctured

Fig. 2.—Showing the method of fastening the tube in the chest by means of tape and adhesive plaster.

wound is then enlarged along the upper border of the rib, *i.e.* between the needle and the rib below it, to avoid wounding the intercostal vessels. This opening is made just large enough to admit snugly the rubber drainage tube which is inserted at once with as little escape of pus as possible.

The rubber drainage tube consists of rather stiff rubber tubing 3/16 inch inside diameter; the wall is about 1/16 inch thick, with a window near the end, and a narrow section, about ¼ inch long, of a slightly larger (¼ inch inside diameter) tube slipped over it as a cuff, leaving about 1 to 1½ inches protruding, just enough to penetrate the chest wall. A piece of tape ½ inch wide and 4 to 6 inches long with a hole, preferably buttonhole-stitched, in its center is threaded over the tube down to the cuff, over which it will not slip.

The tape is securely fastened to the chest with narrow strips of adhesive plaster about 2 inches from the wound. The cuff thus held between the chest wall and the tape makes a tight fit and firmly anchors the tube in place. The application of one or two small gauze pads partly split so as to surround the tube and cuff and fastened to the chest with adhesive plaster completes the dressing. Unless the tube becomes plugged neither tube nor dressing will have to be changed for three or four days.

The rubber tube should be two to four feet long so that it can be easily connected, without tension, to a bottle suspended under the bed or resting on the floor. The bottle contains warm sterile salt solution and has through its stopper two pieces of glass tubing, one just through the stopper and the other long enough to reach nearly the bottom of the bottle. To this long tube is connected the rubber tube from the chest.

The bottle, of about one-pint capacity, though this is immaterial, is one-quarter to one-third full of warm sterile salt solution, which is changed two or three times a day or as often as necessary to keep it fairly clean. The tube is clamped and the end protected with sterile gauze during this process, thus keeping the interior of the bottle, tube, and chest free from outside infection and also preventing a pneumothorax. When a change of tube is required it is advisable to have a duplicate outfit, tube, tape, and bottle, sterilized and ready.

Immediately after putting fresh salt solution in the bottle it is raised to about the level of the chest, or higher if necessary, tilted over in the manner of using a wash bottle in the laboratory so that the warm salt solution slowly runs into the pleural cavity. The bottle is then lowered and the fluid mixed with the pleural exudate flows back into it.

It often happens that the patient's respiratory movements are sufficient, particularly when the bottle is about on the same level as the chest, to produce this in and out flow and thus automatically irrigate the pleural cavity.

If, for any reason, a larger opening in the chest wall is required, as might be necessary in order to break up adhesions or to drain a thick discharge with large masses of fibrin, the usual method of resecting a portion of a rib may be employed with the application of this same principle with correspondingly larger tubes and bottle.

The advantages of this method may be summed us as follows: (1) Operation simple, easy to perform. (2) No shock, due to the simple and quick operative procedure and the slow escape of pus and to the absence of pneumothorax. (3) Single dressing which does not require very frequent changing,

Fig. 3.—Dressing complete; in this case, however, there is more gauze than is necessary.

as there is little, if any, leakage around the tube and in this way the danger of the serious and often fatal complication of a mixed infection in the pleural cavity is greatly lessened. (4) Convalescence has appeared to be shorter. (5) The patients are certainly more comfortable with this method than with any of those formerly employed. (6) This method seems to be particularly applicable to very young children, as it has been successfully employed on babies three months old. (7) The drainage has been very efficient, as the discharge is continually thinned and diluted by mixing with the warm salt solution.

THE DIAGNOSTIC VALUE OF THE USE OF THE SPHYGMOMANOMETER IN EXAMINATIONS FOR LIFE INSURANCE.*

By J. W. FISHER, M.D.,

MILWAUKEE, WIS.

MEDICAL DIRECTOR THE NORTHWESTERN MUTUAL LIFE INSURANCE COMPANY.

The Northwestern Mutual Life Insurance Company, in August, 1907, required the local examiners of the company in several of the larger cities to furnish the company with a blood-pressure reading of applicants examined by them where the applicant's insurable age was 40-60 years. (The company does not insure persons whose insurable age is over 60.) Gradually this requirement has been extended to all localities where it has been possible to secure the blood-pressure reading, so that at the present time the blood-pressure is furnished in all localities in which the company does business, where it is possible to induce the examiner to secure a sphygmomanometer. The blood-pressure is required, regardless of the amount applied for, in persons where the insurable age is between the years forty and sixty, and at any age where the medical department deems it advisable. In our home office examinations the blood-pressure is taken at all ages. We therefore have a record of 420 accepted cases under age 40, with a blood-pressure average of 125.20 mm. Hg. See Table I. In addition, 20 applicants under age 40 were rejected, whose blood-pressure was 150 mm. Hg or over.

TABLE I.—The Average Systolic Blood-Pressure, Accepted Risks at Age 15-39.

Ages	Number	Mm. Hg of Pressure	Average Blood-Pressure
15–19	21	2,478	118.00
20–24	56	6,917½	123.53

Grand Total	12,647	1,646,257	130.17

*Read before the Association of Life Insurance Medical Directors, October 4, 1911.

By reference to Table No. 2 it will be seen that 12,647 persons were insured with an average blood-pressure, at ages 40-60, of 130.17 mm. Hg; at ages 40-44, this average was 128.26 mm. Hg; at ages 45-49, average 130.51 mm. Hg; at ages 50-54, average 131.98 mm. Hg; at ages 55-60, average 134.46 mm. Hg. In all of the readings the pressure was adjusted as nearly as possible to a cuff of 12 cm. in width.

TABLE III.—The Average Systolic Blood-Pressure Risks Accepted Whose Weight Exceed the Average by More Than 20 per Cent.

Ages	Number	Mm. Hg of Pressure	Average
Under 40	21	2,675	127.38
40	76	9,942½	130.82
41	72	9,484½	131.73
42	102	13,440½	131.77
43	87	11,418½	131.25
44	70	9,325	133.21
Total	407	53,611	131.72
45	90	11,994	133.27
46	67	8,882	132.57
47	86	11,644½	135.40
48	83	11,253	135.58
49	52	7,106	136.66
Total	378	50,879½	134.60
Grand Total	806	107,165½	132.96

By reference to Table No. 3 you will find that 806 persons were insured whose weight exceeded the average by more than 20 per cent.; 21 of these were under age 40, with an average pressure of 127.38 mm. Hg; 407 were insured at ages 40-44, with an average pressure of 131.72 mm. Hg, and 378 were insured at ages 45-49, with an average blood-pressure of 134.60 mm. Hg. In all cases where a number of blood-pressure readings were taken the average blood-pressure was used in compiling the tables showing the average at the different ages.

TABLE IV.—Mortality of Accepted Risks with Systolic Blood-Pressure of 140-149 mm. Hg, with an Average of 142.43 mm. Hg, All Ages.

Years	Number	Expected	Actual	Per Cent
1907	217	11.338	4.	35.279
1908	652	30.178	12.	39.764
1909	953	27.800	8.	28.777
1910	846	12.541	7.	55.817
Total	2,668	81.857	31.	37.870

Table No. 4 shows the mortality (taken by the Actuary's Table) of 2,668 insured, with a blood-pressure of 140-149 mm. Hg, was 81.85 expected deaths, 31 actual deaths, a percentage of 37.87, which is slightly below the normal death rate of the company on exposure of two years. It should be stated that the average exposure in all of these cases was 2.09 years, covering a period from August, 1907, to January 1, 1911, and carried up to the anniversary of the policies to July 1, 1911.

Table No. 5 shows the mortality record of 525 persons insured with a blood-pressure reading of

150 mm. Hg and over, with 22.19 expected and an actual of 12 deaths, which is about 35 per cent. in excess of the general average mortality of the company covering the same period, and 18 per cent. higher than the general average mortality during the first five years of exposure covering the 20-year period 1885-1905.

TABLE V.—Mortality of Accepted Risks with Blood-Pressure of 150 mm. Hg, and Over; Average 152.58 mm. Hg, All Ages.

Years	Number	Expected	Actual	Per Cent.
1907	87	4.884	5	102.370
1908	210	10.654	6.	56.317
1909	163	5.547	0	0
1910	65	1.112	1	89.929
Total	525	22.197	12.	54.062

Table No. 6 shows a mortality record of 722 persons declined for insurance, in whom the blood-pressure averaged 171.03 mm. Hg; 20.61 deaths expected, with 32 actual deaths, a percentage of 155.27, almost four times greater than the general average of the company.

TABLE VI.—Mortality of Applicants Rejected with Average Blood-Pressure of 171.03 mm. Hg, All Ages.

Years	Number	Expected	Actual	Per Cent.
1907	40	2.495	9.	360.72
1908	119	6.187	9.	145.47
1909	209	7.253	9.	124.09
1910	225	4.119	4.	97.11
1911	129	.555	1.	180.18
Total	722	20.609	32.	155.27

Table No. 7 shows 356 of the 722 rejected cases in which there were one or more other impairments than the high blood-pressure. The nature of the impairments will be found in Table No. 8. Of the 356 cases, 10.47 deaths were expected, with an actual of 18 deaths, or a percentage of 171.93 of the table.

TABLE VII.—Mortality of Applicants Rejected with High Blood-Pressure (average 171.73 mm. Hg,) and One or More Other Impairments.

Number	Expected	Actual	Per Cent.
356	10.469	18.	171.93

TABLE VIII.—Impairments Recorded on Applications at Time of Medical Examination of the 356 Cases Recorded in Table No. 7 Above.

Arterio-sclerosis — Atheroma	Heart Murmur	Heart Hy-pertrophy	Albumin and Sugar	Albumin in Urine	Sugar in Urine	Albumin and Casts	Casts in Urine	Nervous Symptoms	Prostatic Disease	Miscel-laneous	Total
53	69	17	10	110	14	10	6	21	5	41	356

Table No. 9 shows 366 cases, the remainder of the 722 rejected, in which there were no other impairments than the high blood-pressure recorded on the application at the time of its receipt at the home office. The expected deaths were 10.14, with an actual of 14 deaths, or 138.07 per cent. of the table.

TABLE IX.—Mortality of Applicants Rejected with High Blood-Pressure Only. (Average 170.36 mm. Hg.)

Number	Expected	Actual	Per Cent.
366	10.140	14.	138.07

Table No. 10 shows subsequent impairments reported in the 366 cases recorded in Table No. 9. You all appreciate the difficulty of securing additional data on rejected cases. In all of the rejected cases, especially the 366 noted in Table No. 10, a special effort was made to have repeated readings of the blood-pressure and examinations, with a view to discover, if possible, the probable cause of the high blood-pressure or what might in any way account for it. We invariably called for a specimen of the urine to be forwarded to the home office for chemical and microscopical examination, with the results shown in Table No. 10. In almost all of the impairments in which casts, albumin, and sugar were found, and in some of the heart lesions, these impairments were discovered on examinations made at the home office, or were secured at a later date by furnishing the local examiner who made the original examination with a list of the cases and the name of the applicant's family physician, through whom the local examiner might determine as to the physical condition of the applicant. In some instances the local examiner saw and examined the applicant at a considerable period subsequent to our declination. By this method we have secured recent reports on about 90 per cent. of the inquiries made on declined cases where the applicant held no insurance in this or other companies in the interchange. We have made an effort in various other ways to bring the records up to date on all of these rejected cases. In the same manner, we have endeavored to secure the cause and date of death of those who died.

It will, therefore, be seen that the mortality shown in the tables covering the rejected cases is undoubtedly more favorable than the exact facts would show, as the chances are, with all the care we have taken to follow up rejected cases, that some deaths must have occurred of which we have no record.

TABLE X.—Impairments Subsequently Discovered or Developed in the 366 Cases Recorded in Table No. 9 Above.

Arterio-sclerosis Atheroma	Heart Murmur	Heart Hy-pertrophy	Albumin and Sugar	Albumin in Urine	Sugar in Urine	Albumin and Casts	Casts in Urine	Nervous Symptoms	Miscel-laneous	Total	Expected	Actual	Per Cent.
6	9	4	2	13	5	33	13	6	10	101	3.061	4	130.66

Table No. 11 shows the causes of death of, first, the 525 risks accepted (see Table No. 5) with a blood-pressure of 150 mm. Hg. and over (with an average blood-pressure of 152.58 mm. Hg), the average blood-pressure of those who died being 151.71 mm. Hg, and, second, the 722 cases rejected with a blood-pressure of 171.03 mm. Hg, the average pressure of those who died being 183.61 mm. Hg. (See Table No. 6.)

Three hundred risks were accepted with a blood-pressure of 109 mm. Hg and under, an average of 103.43 mm. Hg, with only three deaths. Of these, 248 were insured at ages 40-50, with two deaths; 52 at ages 50-60, with one death; 1,488 risks were insured with a blood-pressure of 110-119

mm. Hg, with only five deaths; 1,186 of these were insured at ages 40-50, with one death; 302 at ages 50-60, with four deaths.

The local examiners are furnishing the company with blood-pressure readings in their examinations in about 500 cities, towns, and localities in which the company does business.

TABLE XI.

Causes of Death				Causes of Death
Risks accepted as shown in Table No. 5.. Average Blood-Pressure of those who died was 151.71 mm. Hg.	1	Angina Pectoris	2	Risks rejected as shown in Table No. 6.. Average Blood-Pressure of those who died was 183.61 mm. Hg.
	1	Aneurysm aorta	1	
	1	Apoplexy	7	
	1	Arteriosclerosis	1	
	1	Appendicitis	2

	1	Rheumatism—Acute		
	2	Suicide	1	
		Stokes-Adams Disease	1	

The records of this company show that during the period from August, 1907, to January, 1911, the blood-pressure of 13,789 applicants was furnished the company, and that in 1,247 of these cases the blood-pressure was 150 mm. Hg, or over, with a mortality of 102.80 per cent. of the table; 33 of these were under age 40 and the remainder were ages 40-60. The percentage of high tension was about 8 per cent. in the younger group and 9 per cent. in the older group.

Notwithstanding the number of cases under observation at ages under 40 is comparatively small, in my judgment the results are sufficient to justify insurance companies requiring the use of the sphygmomanometer in examinations for life insurance of applicants under age forty, at least until a large number of cases have been under observation for a sufficient length of time to enable us to definitely determine the diagnostic value of the sphygmomanometer at the younger ages.

No practitioner of medicine should be without a sphygmomanometer. He has in this instrument a most valuable aid in diagnosis. The sphygmomanometer is indispensable in life insurance examinations, and the time is not far distant when all progressive life insurance companies will require its use in all examinations of applicants for life insurance.

CONCENTRIC PROGRESSIVE DIMINUTION OF THE AREA OF LIVER DULLNESS IN THE DIFFERENTIATION OF FREE GAS IN THE PERITONEAL CAVITY FROM ABDOMINAL TYMPANITES.

By HENRY W. BERG, M.D.,

NEW YORK,

ASSOCIATE ATTENDING PHYSICIAN TO MT. SINAI HOSPITAL; ASSOCIATE IN PEDIATRICS, COLUMBIA UNIVERSITY; ATTENDING PHYSICIAN TO THE WILLARD PARKER HOSPITAL.

Disappearance of the area of liver dullness and flatness is one of the most valuable symptoms indicative of the presence of free gas in the peritoneal cavity—a condition known as pneumoperitoneum. In this condition, instead of the normal dullness and flatness over the hepatic and splenic areas, percussion elicits at these sites loud, deep resonance. Inasmuch as free gas in the peritoneal cavity, due to conditions such as perforations of the hollow viscera, demands immediate recognition and urgent surgical care, it becomes important for us to be able to differentiate positively such tympanitic resonance, due to free gas in the peritoneal cavity, from a similar tympanitic resonance over the hepatic and splenic areas due to excessive tympanitic distention of the abdominal hollow viscera with no perforation and no pneumoperitoneum. Such differentiation is never very easy, and sometimes very difficult, especially shortly after the perforation has occurred.

The differentiation can be made, however, with approximate certainty on a basis of clinical data which I have learned to recognize from a considerable observation of these cases in recent years. In all cases of typhoid fever, indeed in most medical cases admitted to the hospital, accurate records of the upper and lower boundaries of liver dullness and flatness, as well as the site of the lower border by palpation—if palpable—are kept, including the status at the time of admission, together with all changes occurring from day to day during the stay of the patient in the hospital; so that on the occurrence of the earliest subjective or objective symptoms leading to even the suspicion of perforation we are enabled to compare the area of liver dullness, carefully mapped out both as to the upper and lower borders, with the boundaries present before the suspicious symptoms occurred.

I found that in all cases in which subsequent surgical interference enabled me to confirm the diagnosis of perforation, the earliest suspicious symptoms had been accompanied by a rapid and progressive diminution and final disappearance of the area of hepatic dullness and flatness, the hepatic area becoming tympanitic. This disappearance of hepatic dullness had progressed *synchronously* downward from the upper border of the liver dullness, and upward from the lower border, until the whole area of dullness disappeared and tympany was present where the dull hepatic area had been; the central area of hepatic dullness was the last to be replaced by tympany, the areas of tympany progressing from above downward and from below upward, and finally meeting at the centre. This is at variance with the general conception that in these cases the area of hepatic dullness is encroached upon by tympany from below upward, the last of the area to become tympanitic being the upper border.

When excessive tympanitic distension of the bowel becomes so great as to diminish, or even occlude, the area of liver dullness, the progress of the disappearance of liver dullness is from below upward only; the upper border of liver dullness in cases of moderate distension never disappears, but is displaced further upward at the expense of the area of pulmonary resonance, as shown by comparison with the record of physical examination of the patient, made previous to the occurrence of the distension. Even when the tympanitic distension is extremely marked, careful percussion will generally succeed in mapping out the upper border (however narrow) of hepatic dullness, although relatively high up the chest. Under all circumstances, if the patient is observed during the progressive substitution of tympany for dullness over the hepatic area, it will be found that this tympanitic area moves from below upward, pushing upward before it the upper border of liver dullness which encroaches gradually upon the area of pulmonary resonance.

When, on the other hand, free gas enters the general peritoneal cavity, the air naturally rises to

the highest level in the abdominal cavity. The patient lies with head and shoulders supported by pillows, so that the upper, diaphragmatic portion of the peritoneal cavity is on a higher plane than the lower. The air thus rises in the vault of the diaphragm and fills the spaces between the liver and the diaphragm, both in front and behind, and on either side of the suspensory ligament of the liver, pushing the liver downward and away from the chest and abdominal walls, and the diaphragm, upward.

This upward displacement of the diaphragm results in a compression of the lungs, particularly of the right lung, the base of which in its circumference is forced as far as possible into the sulcus or angular space between the lower ribs and the costal attachment of the diaphragm. The respiration, owing to the conditions present in perforative peritonitis, becomes very shallow, and the circumference of the bases of the lungs thus forced into this space practically suffer cessation of their respiratory functions. The air cells of this portion of the right lung therefore retain their dilated condition and come to lie between the chest wall and the area of the liver which the lung overlies—in other words, the upper area of liver dullness gradually comes to be concealed by pulmonary resonance. Meantime the free gas in the peritoneal cavity, as the patient lies upon his back in bed, also intervenes between the diaphragm and the liver and displaces this organ downward and backward from the diaphragm and abdominal wall. Tympanitic resonance due to the cushion of air thus conceals the lower portion of the area of dullness and flatness present when the liver lies in direct contact with the abdominal wall and diaphragm.

It follows then, that free gas in the peritoneal cavity diminishes to disappearance the area of liver dullness, the progress being simultaneously from above downward and from below upward, the middle of the area of hepatic dullness being the last to be replaced by tympanitic resonance.

It is true that the progress of the concentric diminution to disappearance of the area of hepatic dullness is most readily followed in hospital cases, in which accurate records of the upper and lower boundaries of the area of dullness are kept on the charts and any change is noted, and where the house physician, being constantly present, can follow the gradual progressive change in the percussion area of the liver. Even in private practice, however, cases of intestinal or other perforation of hollow abdominal viscera will show after a short time total disappearance of hepatic dullness, while cases in which diminished area of hepatic dullness is due to tympanitic distension of the intestines will show on careful percussion at least a narrow line of dullness encroaching upon the normal area of pulmonary resonance, higher up than the upper border of liver dullness observed normally in all cases, and in the patient in question at the previous examination. This is due, as has been stated, to displacement of the liver and diaphragm upward by the distended colon.

I have found these data obtained by percussion so valuable as aids in distinguishing between pneumoperitoneum and tympanitic distension of the colon that since I have used them I have never been many hours at fault as to which condition was present in a given case, with the result that the diagnosis of a perforation was rendered certain at a much earlier stage, and undoubted evidences of an existing perforation were always found by the surgeon when the abdomen was opened. Indeed, the skillful surgeons who have operated on the cases thus submitted to them have invariably found the one or more perforations that had caused the pneumoperitoneum which had been diagnosticated.

I do not wish to minimize or negative the importance of the other valuable early symptoms that lead to the diagnosis of pneumoperitoneum, such as rapidly increasing leucocytosis, increased rapidity and pulse rate, symptoms of shock, etc. All of these should be used to clinch the early diagnosis, but of all these no one—in my opinion—gives the same security to the physician of the correctness of his diagnosis of the occurrence of pneumoperitoneum as this symptom which I have outlined, and which may be formulated as the *concentric* progressive diminution to disappearance of the area of liver dullness. In other words, that free gas in the peritoneal cavity is shown by the substitution for the area of liver dullness and flatness, of a tympanitic resonance, rapidly progressing synchronously from above downward, and from below upward, the last to disappear being the mid-area of liver flatness.

923 Madison Avenue.

A PRACTICAL CONSIDERATION OF HYPERCHLORHYDRIA AND HYPERSECRETION.

By CHARLES SUMNER FISCHER, Ph.D., M.D.,

NEW YORK.

The differentiation between these two conditions should be made in every case of chronic dyspepsia with increased hydrochloric-acid content of the stomach. It is doubtful, however, whether it is done in the average case as ordinarily examined. The usual diagnosis reads, hyperchlorhydria, organic or neurotic, according to the history of the individual. To a certain extent this is excusable, for it is the practical method of avoiding the entanglement and confusion of a diagnostic labyrinth which has resulted from attempts at classification or identification of varying degrees and phases of the gastric-acid secretion as interpreted by different observers. In this manner there have developed various supposed distinct types with special features of cause, course, and effect, with the result that the literature upon this subject has become well-nigh unintelligible. The discussion has been intense, but the atmosphere has not been cleared. Secondary phenomena still assume the dignity of diseases, and a comprehensive view of the whole subject is generally lacking. It would seem advisable, therefore, to reconcile conflicting theories to the plain facts of common observation of the practical clinic.

That various types of secretory disturbance may occur is very probable. Undoubtedly, other peculiarities will develop in the course of further speculation, to which special names will be given. In an organ subjected to such a variety of insult in the ordinary daily routine and capable of such voluminous secretion one may expect almost any vagary of function. That each diversion from the normal, however, should be classified as a special type of abnormality is going somewhat astray, for it is more than probable, in the light of ordinary clinical experience, that most of the so-called distinct affections are not justified and exist only as a result of specialistic enthusiasm. It is this mad desire for novelty which often confounds the sane

judgment of broad biological facts underlying all digestive function and produces imaginary conditions entirely at variance with tested physiological laws.

In dealing with native hyperacid conditions in the stomach, we have primarily to do with two changes in gastric secretion—namely, increase in volume or increase in concentration. These two factors stand out as a result of all clinical and experimental observation. In the one case the whole quantity of fluid secreted is increased, with or without augmented percentage composition. In the other the percentage of acid is increased without increase in quantity of fluid secreted. In every case these two states must be differentiated, a proposition which is sometimes difficult in the rapid ordinary routine work of a clinic. In this connection, all the elaborate methods devised in the course of years are useless, even though they were as exact as they are claimed to be, which is very doubtful. By the demonstration of a higher normal percentage of hydrochloric acid in the gastric juice than formerly supposed, the actual degree of acidity has lost some of its diagnostic value. This is especially evident since more experienced clinical observation has shown that the intensity of immediate symptoms and remote effects depends largely upon the volume of the secretion, irrespective of acidity.

To determine the volume of fluid secreted by the stomach during digestion is not an easy matter. The exactest methods proposed for this purpose are either unreliable or would, in any case, be too complicated and impractical for the rapid routine work of a clinic. Hence, in the average type of chronic dyspepsia, the solution of this question depends more upon individual experience and judgment than upon manipulation and technique. There are some rough clinical tests, however, which, if corroborative one of the other and employed with systematic routine, would indicate the existence of a hypersecretion with some degree of certainty.

In any case of primary hyperchlorhydria there is always presumptive evidence that the volume of fluid secreted is increased proportionately. This physiological law is amply supported by the ordinary experience of extraction of gastric contents. In most of these cases the material gushes through the tubes without effort or hindrance, and its subsequent filtration is rapid. Such a character of the specimen may well serve as a hint to the careful observer.

If the subsequent analysis of such material reveals only a slight difference between free and total acidity, the condition may be one of either hypersecretion or hypermotility. The latter may mask the former, and must be determined by further examinations. The presence of these analytical features simply indicates that secretion has continued after the food has been satisfied as to its acid requirements or has left the stomach. Such excess of secretion would represent the gastric juice in its habitual state for that particular individual.

Physical examination will at times lead to a suspicion of hypersecretion. While the ordinary succussion sound in the stomach has lost much of its clinical value, if the same can be elicited markedly at the time of extraction of the various test meals it will be presumptive evidence that an excess of fluid is present. This is especially true in cases where the motility is normal or increased. In these cases the patients themselves may complain of decided splashing within the stomach between meals.

The motility of the stomach has an important bearing upon hypersecretion. If hypermotility is present as a constant factor and the stomach contains acid fluid in appreciable quantity, even though this be small, a hypersecretion can be suspected, for secretion should have ceased at the end of digestion, and any residual fluid carried away with the food.

Hypersecretion must be thought of in those cases where a decided discrepancy exists between the degree of acidity and the intensity of the symptoms. A normal stomach is fairly insensible to considerable variation of temperature and chemical irritation within its cavity. It is especially sensitive, however, to the extremes of pressure from within, be those positive or negative. Clinical observation demonstrates amply that most of the disagreeable sensations of chronic dyspepsia are due to excessive fullness or emptiness. We know that no positive relationship exists between the degree of acidity and severity of symptoms. There is a fairly constant relationship between the volume of the contents and the resulting symptoms, irrespective of acidity. In other words, we may have a hyperchlorhydria without symptoms. We rarely have a hypersecretion without symptoms. In so-called "water-brash" the volume of fluid is increased enormously, and the symptoms are intense, whereas the acidity is usually negative. The stomach usually responds to experimental insult by pouring out increased fluid, the acidity of which may vary to any extent. It may normally be very decided.

In addition to the above observations, we may test the secreting capability of the stomach with the more recent dry meal. Originally proposed to determine the existence of a certain type of hypersecretion—namely, alimentary hypersecretion—it can well be employed to develop the volume capacity of secretion in any case. If such a meal be administered to an individual with normal stomach, the extracted specimen will show a certain but not marked excess of fluid above solid material. According to Strauss, such contents should reveal a half and half proportion upon standing. This he calls the normal "Schichtung's Quotient." In cases of hypersecretion a decided discrepancy will appear between sediment and fluid. The test is useful in that it reveals not only the volume of secretion, but also indicates the habitual degree of acidity attained by the gastric juice. This is as nearly unadulterated as it can be obtained by rough clinical methods. The method has its limitations like all others. A fertile source of error lies in the possible absence of homogeneity of the contents themselves within the cavity of the stomach. In such instances—and there is no way of guarding against them—the relative proportions of sediment and fluid may give false impressions as to the actual conditions. Hence this method should only be employed comparatively and in connection with the others already noted.

The impression one receives from the perusal of the literature as to the various types of excessive native acid secretion in the stomach would foster the belief that, given certain conditions of digestive abuse or deficiency, there always must result a distinct type of secretory disturbance natural to such conditions. In this way a variety of secretory anomalies have been conceived, based upon the direct relationship of cause and effect. In other

words, given such and such conditions, such and such secretory anomalies must necessarily follow. The result has been the adoption of more or less fanciful data as necessary foundations for the production of distinct types of abnormal secretion, both causes and effects being judged according to individual conception and preference.

To counteract this speculation we have the practical experience of the average clinic. The impression here received from observation of large masses of material, from study of the histories of cases as ordinarily presented, involving the common practices of everyday life, is that the finer adjustment of special causative factors to the production of specific clinical types of abnormal secretion is more or less fanciful, that the differences found are probably matters of accident or individual peculiarity, dependent upon special features of environment or habit, which always exist in each case. Whatever these may be, and dependent upon their duration, there is revealed at the time of examination an anomaly of secretion which represents only a certain stage of a progressive disturbance, which will at some period of its development give all the signs and symptoms of any one of the various types described by different authorities. Viewed in this light, the several types of hyperchlorhydria or hypersecretion would represent only a certain stage of advancement of one and the same general process. In this connection it is interesting to note that, while the various authorities insist upon the special features of their selected types, they are almost universally agreed that they are all produced by about the same causative conditions and that treatment is practically the same for all. It may be stated here that it is immaterial what the original producing cause was. Whether physicochemical or psychoneurotic, the time comes in every case when the two become so merged in the remote effects that they are absolutely retro- and interactive. Original neurotic or organic conditions generally fuse to form vicious circles in their usual chronic courses.

The practical question involved is: Have we in the various types of gastric hyperacidity separate clinical entities or are they simply different degrees of one and the same process? Such a conservative teacher as Boas believes that a chronic hypersecretion may exist as a primary condition, that an original insult to the gastric mucous membrane can result in a continuous pathological secretion from the beginning. There are no clinical data to refute this conception. This would require continuous observation upon a series of such cases from the time of the first insults to the completion of the process. The conception is justifiable, but not entirely reasonable. Viewed in the light of daily practice and the habits of the average individual, it is more probable that the original attacks were isolated and indistinct and have been forgotten. In dealing with an organ so peculiarly insensitive as the stomach, it is possible to conceive that pernicious influences may be at work for years producing changes without adequate perception on the part of the individual. Such perception may be postponed until the process becomes very pronounced or a necessary physiological setting is present. These two conditions arrive sooner or later in most cases, and examining at this moment we may find a complete picture of one of the prevailing types, which represents, however, only a certain stage of a common process. Transient conditions of hyperchlorhydria can very well escape notice. This is entirely an individual matter, dependent upon local sensitiveness and general susceptibility.

The tendency of every normal stomach is to hypersecrete upon insult, and if the latter are frequent enough, a habit of hypersecretion may be established. Arrived at this stage each digestive act is accompanied by an excess of secretion and the intervals between the occasional attacks of ordinary hyperchlorhydria are shortened. In this manner a permanent condition of hyperchlorhydria is developed. Such individuals always exhibit an excess of acid with each food ingestion. They may or may not exhibit symptoms of the condition. These stomachs always empty themselves between meals and no acid is found. These cases represent by far the greatest class of our chronic dyspeptics and give the common symptom-complex of gas eructations, pyrosis, and painful pressure coming on at the end of the digestive act. In this condition they may remain stationary for years.

There is always danger, however, that this more or less physiological hyperchlorhydria may develop into a hypersecretion by extension into the interprandial periods. Upon this conception the diagnosis of hypersecretion is based. Such extension may be apparent or real. It is real only when the motor functions of the stomach remain normal. In the advanced stages of excessive acid secretion, when motor interference of one sort or another has been established, it is generally impossible to say which condition is present. The volume of the gastric contents at this stage may be due either to retention or hypersecretion. The differential diagnosis can only be made early and all the arguments constantly advanced as to the obstructive nature of the Reichman complex are necessarily futile. With retention once established the determination of excess volume and acidity need not indicate a hypersecretion.

A positive diagnosis of hypersecretion *per se* postulates a normal motility. There can be neither retarded or accelerated muscular activity of the stomach. In the first instance the excessive secretion may well be a mechanical manifestation; in the second it may be only apparent. Attention of late has been directed to the relation existing between hypermotility and hypersecretion. It should be remembered in this connection that the same influences which affect the secreting structures also affect the muscular structures. It is not reasonable to suppose that causes activating the one function should depress the other. Clinical experience confirms this, for the early association of apparent hypersecretion and hypermotility is a matter of common observation. Such stomachs empty themselves very rapidly, but contain acid fluid within the normal digestive period following ingestion. Analysis of this fluid reveals only a slight difference between free and total acidity. To diagnose hypersecretion in all such cases would be manifestly an error, for the volume of the secreted juice may be directly proportional to the original stimulus. If this physiological secretion leaves the stomach within a reasonable time after meals, it need cause no special symptom or disturbance. Such stomachs exhibit an excessive but physiological activity. In this condition they may remain for years.

There is always danger, however, that the motor functions may be affected eventually. It should be remembered that the tendency of every hyperacid

stomach is toward retention. It is a physiological process in the beginning, instituted for protective purposes. Excessive gastric acidity must induce prolonged pyloric contraction. The duration of this reflex act stands in direct relation to the quality and quantity of the gastric juice. In itself it is purely a very active normal function. The time will come, however, when the passage of food will be retarded little by little and a vicious circle established within the organ itself. The retained food increases secretion, which, in turn, prolongs pyloric contraction and increases retention. Arrived at this stage, we have the familiar combination of hypersecretion with retention, but this result has been attained gradually by more or less physiological processes. Judging from practical observation of large clinical material and the examination at all stages, the development of these conditions is along fairly fixed lines. The primary insults induce hyperchlorhydria and hypermotility. As a result of the latter the stomach contains acid secretion during the interprandial periods. This, in turn, induces prolonged pyloric contraction. The time comes when food is retained. This causes additional secretion and the combination is complete. The degree of development and the relationship between the secretory and the motor functions will depend more or less upon the period of examination.

It can readily be appreciated that the diagnosis of a primary hypersecretion presents certain difficulties. All the aspects of each case must be taken into consideration, and it is more than probable that some of the distinct types are more or less fanciful, and that they represent for the most part certain stages of development of one and the same process. The initial stages are usually not observed and represent the mass of attacks of acute indigestion, "sour stomach," and so-called bilious attacks from which people suffer in the course of their daily lives, and which yield to ordinary domestic remedies. It is not reasonable to suppose that a definite relationship of cause and effect, tending to the production of distinct types, exists in most cases. The histories of the majority of these cases are similar. The insults to the gastric mucous membrane are delivered either directly or indirectly—that is, they are either physiochemical or psychoneurotic—and they are common to all classes. It is only in the rapidity with which the final result is reached that the cases differ. This is a matter of individual resistance. In the beginning the organ always returns to normal between the attacks, but, unless supervision is exercised, an occasional hyperchlorhydria may become habitual and develop into a hypersecretion with all the attendant evils of compulsory and physiological retention. The last may appear contradictory, but it should be remembered in this connection that the act of retention in itself in these cases is purely physiological, whatever may be the pathological features of the results of this act.

The time has arrived when we are in a position to take a broader view of such conditions as hyperchlorhydria and hypersecretion, thanks to a mass of clinical and experimental evidence, and we should eliminate certain fanciful conceptions which have resulted from the enthusiasm attendant upon the exploration of a comparatively new field.

THE PROPHYLAXIS OF THE OROPHARYNX AND NASOPHARYNX.*

By J. H. GÜNTZER, B.Sc., M.D.,

NEW YORK,

ASSISTANT SURGEON, MANHATTAN EYE, EAR, AND THROAT HOSPITAL; ADJUNCT PROFESSOR OF OTOLOGY, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

It is my purpose to call your attention to some of the pathological conditions involving the oropharynx and nasopharynx, particularly to such as accompany the acute infectious diseases, incidentally mentioning two conditions, the one an infection *per se*, the other the result of hypertrophic changes in the lymphoid tissues of this region. Aware that little can be advanced which is new, it will, however, be profitable, even at the expense of repetition, to point out the conditions that may be overlooked by the practitioner or else are regarded by him as of minor importance, yet these conditions often lead to serious consequences, which, if they could not have been entirely avoided, at least could have been ameliorated by careful prophylactic treatment. Diphtheria, syphilis, tuberculosis, and local benign or malignant conditions of the oropharynx or nasopharynx will not be considered here, since the local manifestations of these are apparent and are usually looked for or are indicated by the clinical history of the case. In scarlet fever combined with a true or pseudodiphtheritic throat, treatment is directed locally, but in the ordinary case of scarlet fever without such a clinical picture and in the case of measles, whooping cough, typhoid, etc., the treatment of the nasal and pharyngeal cavities is more frequently neglected.

Let us consider the importance of the local conditions, limited to the oropharynx and nasopharynx in some of the infectious diseases. With few exceptions, such as typhoid, paratyphoid, cholera, dysentery and bovine tuberculosis, which gain their entrance into the system through the digestive tract and some other infections that enter the blood through the skin as malaria, yellow fever, uncinariasis, and others having a parasite or protozoan as the etiological instigator, it is conceded that the causative microorganisms in a majority of the infectious diseases enter the body through either the lymphatic or vascular system, and that the portal of entry in most instances is through the mucosa or else through the lymphoid structures of the upper respiratory tract. In epidemics of cerebrospinal meningitis, the *Diplococcus intracellularis meningitidis* has been repeatedly found in the nose and nasopharynx of those associated with cases of this disease; we know that the disease is usually preceded by an acute rhinitis. In poliomyelitis, which no doubt is caused by a microorganism as yet unidentified, secretions from the nasopharynx injected into laboratory animals have produced a similar clinical condition as accompanies this disease in man. In scarlet fever, virulent streptococci invariably abound on the tonsils, and in about one-half of the cases a membrane is found often associated with diphtheritic infection. With measles, we have a more or less pronounced catarrhal condition invading the upper respiratory tract with a variety of microorganisms in the secretions, and while it is usually considered a mild disease, we know that it is frequently followed by serious complications and often by fatalities. In whooping cough and mumps

*Read before the Greenwich, Conn., Medical Society, June 7, 1911.

the nidus of infection is probably somewhere in the oropharynx or nasopharynx. The insidious streptococcal tonsillitis usual at the beginning of rheumatism is often overlooked. With follicular tonsillitis the streptococcus is usually the offending organism, and through the tonsil may cause a systemic infection with endocarditis.

In most of these diseases the streptococcus is the particular microorganism which adds to the seriousness of the infection, and although not the specific agent it is undoubtedly the cause of the more frequent and graver complications, since it is known to show a predilection for the serous surfaces or cavities. Beginning primarily in the nose, pharynx, or tonsils, the streptococcus infection may extend to any one or all of the accessory nasal sinuses, to the middle ear, and to the meninges, either of which may be accompanied by a streptococchemia. Ordinarily the middle ear is more often contaminated than the nasal sinuses. In scarlet fever the percentage of purulent middle-ear disease is highest (about 20 per cent) and half of the number of cases, or 10 per cent, are found in diphtheria, measles showing about 5 per cent. of the cases, and here the infection seems to be milder than in the other two; it is most severe in scarlet fever, where about half of the cases show a bilateral involvement. In typhoid fever, and pneumonia too, a purulent middle-ear complication not infrequently arises.

There is a further affection, not an accompaniment of the infectious diseases which constitutes an infection *per se,* whose initial clinical manifestations begin in the oropharynx. A purely streptococcal infection of the throat would not be a rare affection were it more frequently recognized. It often simulates the early stage of typhoid fever. The patient complains of slight soreness of the throat, which on inspection merely shows a redness of the pharynx, tonsillar pillars, and tonsils; sometimes the tonsils have one or more ill-defined, pale, membranous exudates. The temperature is rather remittent, as a rule not higher than 102° or 103° F. in the evening and falling in the morning to nearly normal. Vomiting during the first few days has been noted, and the bowels may be loose or constipated. There is more or less prostration, varying according to the resistance of the patient; with low resistance usually, if carefully watched, within a week or ten days an endocardial murmur will be detected, and this fact marks the seriousness of a streptococcal sore throat. The writer believes that many a valvular heart lesion or acute nephritis that cannot be related to any particular causation is the result of an unrecognized streptococcal throat infection, and hence the importance of being on our guard to meet this condition and so prevent any permanent cardiac or kidney damage.

With the formidableness of these not infrequent infectious complications before us, it would almost seem unnecessary to emphasize the urgency of instituting prophylactic measures in order to combat the virulency of the offending microorganisms that may be harbored in the mucosa and in the lymphoid structure of the oropharynx and nasopharynx, and of limiting the fertility for their growth and propagation by the radical removal of all diseased lymphoid tissue during the quiescent stage, when free from acute infection. Indeed, this really is the primary and most essential factor in the prophylaxis of this region. We should consider the lymphoid ring of the pharynx an incubator for most of the infectious diseases. Recurrent inflammatory processes of these lymphoid tissues change them pathologically and favorably for bacterial invasion, and also change them into reservoirs supplying the adjacent and remote lymphatic and glandular chains and aiding in disseminating the microorganisms into the general circulation, and so to the various organs of the body. Aside from the usual indications for the removal of tonsils and adenoids, it is recommended by the writer as a means of combating the spread of tuberculosis, to remove the diseased tonsillar and adenoid tissue in all children who are exposed to this disease in families where a member is afflicted with tuberculosis. Following an acute attack of rheumatism, it is recommended to remove tonsils and adenoids so that subsequent attacks may be frustrated. We all have seen a puny, cachectic child bloom into ruddiness and ruggedness soon after the removal of the diseased tonsillar and adenoid tissue which had supplied the system with the toxin that created a constant, slow-fed autointoxication.

Cognizant that the diseased processes, bred or originating in the oro- and nasopharynx as outlined above, may eventuate into a general systemic infection, and that local measures alone cannot abort or reach the true seat of inflammation, it may be admitted, however, that local antisepsis can mitigate the process to the extent of inhibiting the local growth of the pathogenic bacteria, and also can limit the amount of septic or toxin absorption. Cleansing of the nasal, pharyngeal, and oral cavities with an alkaline antiseptic solution, diluted to proper strength (a half or one quarter) made from the liquor antisepticus, U. S. P., preceded by a one in three dilution of peroxide of hydrogen in either cinnamon or peppermint water, or a 2 per cent. solution of sodium perborate, using these solutions as a gargle and spray, will aid in removing the macerated epithelium and contaminated secretions; it is a good plan to paint the mucosa of the nasal and pharyngeal cavities two or three times a day with a 25 per cent solution of argyrol or any other agent that may have bactericidal qualities. Attention to the elimination by the emunctories, skin, kidneys, and bowels is important. Water should be used plentifully both internally and externally. Urinary and heart examinations should be carefully and repeatedly made. Insist on rest in bed in any case, may the throat symptoms appear ever so mild. To antagonize the systemic infection, the injection of an appropriate serum to meet the exigencies of the case, usually an antistreptococcus serum or else an autogenous vaccine, is indicated and medicinally guaiacol carbonate or urotropin in the required doses should be used internally, as well as the Credé ointment of colloidal silver by inunction; this may be prescribed in ten-grain doses in oiled or waxed paper, using one for each rubbing, the attendant to rub it into one of the joint flexures for ten minutes with the gloved hand.

By carrying out such a plan of local and general treatment, an advancing infectious process or its sequelæ can be made regressive, and in many instances the treatment is both prophylactic and curative. Especially in the exanthemata must we direct local treatment to the nose and throat, thereby often preventing middle-ear disease and intracranial complications, and by this means also conserving the sense of hearing. During the prevalence of epidemics of either cerebrospinal meningitis or poliomyelitis, I would especially advocate regular and stringent local cleansing and antiseptic measures to

the nose and pharynx of both the child and adult. Internally we should administer urotropin, since this is known to circulate in the internal secretions and blood and so can exercise its bactericidal qualities. I believe that in this way much can be done to limit the spread of these diseases.

In concluding allow me to briefly mention a pathological condition of the pharynx, not ranking in importance with the described infectious processes, yet one that merits inclusion in this paper, being pertinent to our subject. In cases of persistent cough, hypertrophy of the faucial, pharyngeal, and lingual tonsils is often overlooked, and with a persistent cough the physical examination should not end with "going over the chest," but the mouth and pharynx should be inspected in every case. Thickening of the lymphoid tissue at the base of the tongue (so-called lingual tonsil) often impinges on the epiglottis and is responsible for many a case of intractable cough and sometimes for asthmatic seizures; an elongated uvula is often the offending factor. These conditions are by no means prevalent only in the adult, but are sometimes found in children. These patients complain of a fullness in the throat and have the sensation of a lump being present, which they attempt either to swallow or to cough up and expectorate. Neither attempt is successful. The harrassing cough and vain attempts to rid the throat of this irritating mass often show their constitutional effect. The patient is depressed, has little appetite, soon loses weight, and suffers from loss of sleep because these attacks are worse in the recumbent posture; these patients are often thought to be tuberculous, yet recover wonderfully when the offending causative factor is removed. The physician prescribes through the whole gamut of cough remedies without relief—and the only relief is the removal by ablation or electrocautery of the mechanically irritating tissues of the oropharynx.

A CASE OF ASPIRIN POISONING.

By DAVID I. MACHT, M.D.,

BALTIMORE, MD.

Aspirin was introduced into medicine by Dreser some dozen or so years ago. The drug, which is acetyl-salicylic acid, with the chemical formula $C_6H_4O.C_2H_3O.COOH$, is a substitution-product of salicylic acid, and was recommended as a substitute for salicylic acid and sodium salicylate in rheumatic cases, as causing no untoward symptoms and by-effects. The reason for its lesser irritability was experimentally shown by Dreser (Pharmakoligisches über Aspirin. *Arch. f. d. ges. Phys.*, lxxvi, 306). He found that the compound is affected little or not at all by weak solutions (2 per cent.) of hydrochloric acid, but that it quickly disintegrates in the presence of a weak alkali. He therefore argued that the drug passes unchanged without irritating it, through the stomach, and begins to liberate the salicylic acid slowly, only after it has come in contact with the alkaline contents of the intestine. The drug was quickly taken up by the profession, and extravagant claims were made for its virtues. Liesau, for instance, wrote in the *Deutsche medizinische Wochenschrift*, No. 21, 1900, that "it has a pleasant taste, does not attack the stomach, causes only rarely any ringing in the ears, and has a safe and prompt analgesic and antipyretic action."

The truth, however, is that aspirin is not devoid of toxic action, and may often produce vertigo, ringing in the ears, vomiting, depression, etc., as noted by careful clinical observers, such as noted by Gazert (*Deutsches Arch. f. klin. Med.*, lxviii, 142). Occasionally it may cause symptoms of a more toxic nature. I have recently had an opportunity of observing such a case which, from its rarity of occurrence, I think worth while reporting:

M. I. L., aged 30 years, Dentist. Patient is an athlete and a man of admirable physique and hardened constitution. His family history is negative. He has never been seriously ill, except for an attack of gonorrheal urethritis, for which he was treated and cured. He drinks very moderately and does not smoke. He consulted me three times within the past year for myalgic pains in the back, and was each time given aspirin, with the same results. The first time he received the drug in the form of powders, 10 grains each. Soon after taking one powder he felt "sore" in the stomach, but not nauseated, and did not vomit. His chief complaint, however, was a feeling of constriction around his throat, as if he were choking, and of salivation. The latter he described as thick and ropy mucus gathering in his mouth and causing him to spit. There was difficulty of speech and in deglutition. He also had a headache or constriction in the head, and a congestion of the nose "as if he had a cold there."

On the second occasion the patient took one 5-grain tablet of aspirin about 6 o'clock in the evening. He awoke about 3 A.M. with a feeling of choking, or "constriction around the neck," as he always describes it, and was again salivated, or rather spat thick ropy mucus.

On the third occasion I gave the patient two aspirin capsules of 5 grains each, purposely telling him that I was giving him a different drug. This was done partly in order to make the patient take the substance, as he strongly resented repeating aspirin on account of its affecting him so disagreeably, and partly in order to exclude any mental element that there might be added in describing the effects of the drug. The same result, however, was noted. Some four to six hours after ingestion he had his constriction and salivation. He was, moreover, depressed to some extent on each occasion. On examination, there was reddening of the pharynx and a general edematous condition of the tissues of the neck.

I have looked over the literature on the subject in search of similar cases, and have been able to find only three cases presenting such a picture. Hirschberg (*Deutsche med. Wochenschrift*, xxviii, 416) reports a case of aspirin poisoning with congestion of nose and swelling of eyelids, edema of the pharynx, and salivation with thick mucus. Otto (*Deutsche med. Wochenschrift*, 1903, xxix, 123) reports a case of aspirin poisoning with "constriction" or edema of the throat, difficulty of speech and deglutition, and salivation. There was also a papular eruption on the skin. Meyer, in the same number, page 124, reports a similar case.

I may note that in all these three cases the doses of aspirin administered were much larger than in mine. I did not notice any special skin eruption in my case, although one occasion when the patient took the drug, he did have a few vesicles which he could not account for. Neither was there any irritation of the kidneys noted.

THE MEDICAL STUDENT AND HIS BOOKS.

CONSIDERABLE experience with the students of four of the leading medical schools in America has led the writer to believe, among other things, that many, if not most, such students use too few text-books while in school. The soundness and the importance of this belief will be obvious and this discussion more effective if certain considerations be set forth decently and in order. We may cite two main causes of this state of things anomalous in an earnest profession and an exacting one; one of them is purely human, and the other pedagogic, As human beings who are the chosen teachers of mankind in most important subjects, students of medicine should be interested in both causes, and seek the remedy.

1. Of all students on this earth (unless it be those of art?) medical students are most emphatically and consistently, that is, continually, "broke." This must be owing to the extreme interest that the embryonic physician takes (more or less) professionally in every phase of human nature, leading often to his over-frequenting of theatres, music halls, etc., and to his over-indulgence sometimes even in what Sam Weller calls conviviality; over-generosity in tips to his landlady, on the other hand, probably is not largely concerned. This root of the matter we can fondly wish, but hardly hope to see immediately improved. Its consequence meanwhile in the respect of which we are speaking is that all too often the rather expensive text-books on medical subjects offered in the shops are as consistently passed by as is the contribution-box in meetin'. It need only be remarked that in the active, not to say vehement, struggle for a competent practice later on, when collections are low and the groceries high, the value of acquaintance with the standard text-books on the subjects of the medical curriculum at best fairly rivals the value of acquaintance with human nature and "the world." The average medical student cannot, of course, be taught this fact and it is not expected that he can; he must learn it for himself, each of him and her, by personal experience, but observe, only when it is too late to be of the best use. But none the less, knowledge retains always the greater part of a young physician's capital and his income, therefore, is more or less proportional thereto; the more of this capital, plus personality, the lower down the opera seats and the higher up the auto charges allowed madam and the kiddies later on. This basal-knowledge sort of capital, in the six or eight fundamental subjects at least, is derivable very largely only from text-books. And text-book expense is relatively small after all. An income of $1,500 represents a capital of say $30,000, and one of $5,000, $100,000. Compared with this, forty or fifty dollars a year, while a student expended for extra and adequate books is obviously of trifling account. As for the occasional medical student who buys no books or only the absolute minimum of cheap ones (second-hand or compends) his myopia and mistake are too obvious to need more than admonitory mention. A young man with so narrow an idea of the science of human medicine as that would be better, and probably more lucratively, employed at some useful trade, such as conducting a trolley car, rather than studying a profession. The medical schools have never at best been over-discriminative in the material they accept for their doctorates, as many facts, this among the rest, suggest.

2. The major premise, so to say, of our conclusion, that students use too few text-books, was that the chief reason is a pedagogic one. This rests on a principle of psychology as well as on common sense. The common sense aspect of the matter is obviously that an abundance of ideas represented by several different books on a subject would insure one a better medical education, other things equal. How important this is might be discussed, but there seems need only to remind the reader that mastery of a subject progresses in geometrical ratio with the facts acquired. The pedagogic principle underlying the matter, simple enough, but important, is that even the same facts and theories stated by different educators and, therefore, in different ways, are more easily fixed in the mind (owing to the additional richness of the associations) than if stated to the student by one man in only one book. The importance for easy and permanent learning of this variety of statement it would be hard to exaggerate. In addition, of course, every writer on a subject states facts, if not theories, omitted by the others, and so the actual knowledge derivable from various books is greatly augmented. The same obviously is true of the illustrations in the text-books, and in general their importance as a means of teaching is rarely appreciated at their true high value.

The habit of selling the text-book on a subject when that course has been "passed off" is another custom usually regretted in after years. At times when a dollar looks as large as a moral law the temptation to part with a school book may be considerable to be sure; yet, if students realized how greatly in later and more opulent years they would prize these companions of the dear student-life days, they certainly would never part with them for a little money, but rather keep them as the prized nucleus of the future medical library in the consultation room. For hasty reference purposes, in knotty cases of practice, the old books often have far more value than newer ones owing

to their owner's thorough familiarity with their arrangement and details. Moreover, in the early years of practice the purchase of new books is apt to be a financial burden and many a busy man has regretted the loss of volumes almost given away in over-sanguine (or indigent?) moments years before. Even an old bird in the hand is worth a whole flock of young ones, sometimes, in a distant book store or library.

TUBERCULIN TESTS.

So much has been written about the use of tuberculin for diagnosis since the appearance of the cutaneous and ophthalmic tests with this substance that the busy practitioner of medicine has been overwhelmed with the arguments for and against each method and its reliability. A sober statement of facts, as observed by a man commanding a great deal of material, is, therefore, welcome, and such a statement is given by Lawrason Brown, in the October number of the *American Journal of the Medical Sciences*. Brown considers the specificity, the danger, and the accuracy of tuberculin tests. The specificity of the test is practically absolute. Among laboratory animals only those which are tuberculous react to tuberculin; healthy human beings, babies, for example, having no tuberculous inheritance, fail to react to large doses of tuberculin; among the sick only lepers show a tendency to react to this toxin, but even in this case the reaction differs in character from that observed among the tuberculous.

Danger in the use of tuberculin is present in the employment of the ophthalmic tests, several unfortunate accidents having been reported; the danger, however, is much diminished by excluding all patients from the test who have ever had any trouble with their eyes. The cutaneous test has very rarely given rise to a lymphangitis or a lymphademitis; in the overwhelming number of cases, however, it has proven a safe method. The subcutaneous test, demanding a general reaction, has frequently resulted in a prolonged and severe malaise; it has often brought on increase in the physical signs of the affection; it has been blamed for the "activation" of the disease even to the extent of resulting in the appearance of tubercle bacilli in the sputum, an accusation which Brown is very loth to accept.

Of great importance is the discussion of the accuracy of tuberculin tests. The cutaneous test is most valuable in early life bfore the age of seven or eight years; after that, a positive reaction is of little meaning, for it fails to distinguish between tuberculous infection *per se* and clinical tuberculosis. Brown's conclusion with reference to the ophthalmic test is as follows: In any individual patient, if he react to one drop of a 1 per cent. or of a 5 per cent. solution of old tuberculin given in different eyes, he is more likely to have clinical tuberculosis than if he reacted only to the cutaneous test. The intracutaneous method still remains, perhaps, the most accurate test of the three. Negative skin reaction does not exclude tuberculous infection or even clinical tuberculosis, while failure to react to 10 mg. of old tuberculin, given subcutaneously, probably means, according to Brown, that treatment is unnecessary.

It is seen, thus, that tests with tuberculin have practically no such absolute values as have been claimed for them by many enthusiasts. Often enough, they only add confusion to the clinical data which, after all, must be used as criteria for action. As Brown concludes, no modifications of the tuberculin test "differentiate clearly clinical tuberculosis that demands vigorous treatment, from non-clinical tuberculosis, that requires only a God-fearing life."

TOXEMIA OF PREGNANCY.

One of the greatest sources of confusion in dealing with this subject is the considerable number of toxic substances which might be at fault. These could arise from the food, from intestinal putrefaction, from catabolic products of the mother, from the placenta, from the fetus, etc. Another source of confusion is the number of defensive and eliminative structures which might be at fault. The liver is the organ principally accused, but the kidneys and certain ductless glands are not far behind, and if not primarily at fault the kidneys seldom fail to be involved in the toxemia. This takes no account of merely mechanical pressure disturbances of the intestine, urinary system, and lungs—all of which militate against proper oxidation and elimination. The prevalent belief is that the pregnant woman is ordinarily able to defend herself from the operation of toxic influences through the formation of antibodies. The neutralization is very often incomplete, so that the petty morbidity of pregnancy so-called is commonly in evidence. The less the degree of neutralization the more severe the symptoms; in rare instances there seems to be no attempt whatever at defence, so that even early in pregnancy death rapidly sets in during apparent health.

At a recent meeting of the physicians of the City Hospital at Frankfurt (*Münchener medizinische Wochenschrift*, September 2), Mosbacher reported a case of pruritus gravidarum in which he effected a rapid cure by injecting the serum of a pregnant woman which presumably contained the protective antibodies which the affected woman lacked. In speculating on the nature of the underlying toxicosis the author announced his adhesion to the syncytial theory. It is a fact, however, that some of the most deadly cases of toxemia have occurred long before syncytial tissue could have formed, so that it would be necessary to accuse the cells from which the syncytium develops, which cells have also been accused by embryologists of being somehow responsible for malignant growths in later years, just as they are responsible for chorioepithelioma in connection with gestation.

Diabetes Insipidus.

It has long been the fashion among certain clinicians to deny the existence of an essential polyuria. For them diabetes insipidus is simply a secondary polyuria or pollakiuria of one kind or another. One

clinician sees only the polyuria of contracting kidneys, another a reflex polyuria, a third the evidences of enlargement of the prostate, which mimics an increased excretion of urine, a fourth a merely neuropathic polyuria, etc. It is therefore a matter of great interest to note that Stuber at a recent meeting of the Freiburg Medical Society (*Deutsche medizinische Wochenschrift*, July 27), describes a true essential polyuria, which he terms insipid diabetes, and which was due to increased adrenalin content in the blood as shown by the frog test. The proportion was from two to seven times that normally present. There was a definite relationship between the adrenalinemia and polyuria. There is, therefore, very probably an essential polyuria from overaction of the chromaffin system. It is not commonly known that with a high degree of polyuria some glycosuria may be transiently present. In other words the two types of diabetes shade into each other, thus justifying the old nomenclature. This association is readily understood if we bear in mind that an increase of the adrenal principle in the blood may also cause glycosuria, doubtless by overantagonizing the pancreas. A symptom of diabetes insipidus is intolerance of sodium chloride which readily sets up salt fever.

Disturbances of Metabolism in Nervous Diseases.

It has long been known that metabolic disturbances occur in neuroses and psychoses, and not long ago a monograph was written on the subject by Kaufmann, in which, however, only psychoses were discussed. We know less about metabolism in neuroses and, therefore, it may be of interest to note a discussion on this subject held in the biological section of the Aerztliche Verein of Hamburg last June (*Münchener medizinische Wochenschrift*, August 29). Stoelzner agreed with Hirschstein, the author of the paper, as to the existence of an oxypathic element, with especial reference to unsaturated phosphoric acid compounds. Trömner implied that a study of periodic psychoses and neuroses would furnish a key to the situation, as metabolic disturbances should precede, accompany, or follow these attacks. Metabolic disturbances, while present in various psychoneuroses did not tend to follow definite types. Changes in calcium or phosphorus metabolism had not been sufficiently studied with reference to the diet. We could build up a thin or reduce an obese patient by feeding, yet his disease might not be improved. A patient with neurasthenia might be readily cured without reference to his metabolic processes. Hirschstein said that too much stress seemed to have been laid on the mere retention of phosphoric acid. It was much more important to consider the nitrogenous acids or so-called proteinic acids. There might, of course, be an acidosis—an acid intoxication—to which a number of acids could contribute. Given an essential acidosis, we could determine the secondary consequences, the effects of diet, etc., and so reach a special type of disease.

Deafness Following Purpura.

It has long been known that deafness sometimes follows purpura hemorrhagica, peliosis rheumatica, and similar hemorrhagic conditions, and also that hemorrhage limited to the labyrinth is by no means rare. But not enough attention has been paid to the connection between the two phenomena, probably because in the latter of the two a slight trauma is the cause, and the syndrome of Ménière asserts itself as the true disease, overshadowing the mere initial hemorrhage. Sirgar was the first to note in purpura hemorrhagica an ear syndrome, made up of vomiting, tinnitus, and deafness. Most of the patients promptly recovered, but one, a child, did not fare as well, being left permanently deaf and ultimately dumb. Güttich recently reported a case before the Physicians of Charité Hospital, Berlin (*Berliner klinische Wochenschrift*, August 28). The woman had rheumatic purpura, and the ear syndrome comprised tinnitus, vertigo, and incoercible vomiting. Meningitis could be excluded. The woman became deaf and dumb for a time, suffered greatly from vertigo, and developed nystagmus. Nevertheless she improved much, while troubled somewhat with recrudescence of ear symptoms. It is evident that the mechanism of these purpuric complications is by no means clear, and the belief that they are due to hemorrhage is thus far speculative.

News of the Week.

Civil Service Examination.—The New York State Civil Service Commission announces an examination to be held on November 11, 1911, for the purpose of filling vacancies in the position of physician, either regular or homeopathic, at a salary of $900 to $1,200 with maintenance, and in the position of physical instructor (woman) at a salary of $600 and maintenance. Detailed circulars and application blanks may be obtained from the State Civil Service Commission, Albany, N. Y.

City's Low Death Rate.—For the week ending October 7 the death rate in New York City was 12.60 per 1,000 of population, a decrease of 1.88 points, as compared with the corresponding week of last year, and the lowest rate ever recorded in New York. The low rate of mortality during the week was due to a decreased number of deaths at all the different age groups, not being confined to any particular period. No deaths from scarlet fever or measles were reported, an occurrence unprecedented in the history of the Health Department. Every preventable cause of death against which the Department of Health has been directing its energies showed a considerable decrease, while deaths from causes not so amenable to sanitary surveillance, such as heart disease, pneumonia, diseases of the kidney, and violence, remain fairly constant.

Medical Colleges Consolidate.—Announcement has been made of the consolidation of Barnes Medical College, St. Louis, and the St. Louis College of Physicians and Surgeons. This action was taken following the discrediting of the two schools by the Missouri State Board of Health, and it is hoped that the combination of the equipment and the organization of a new and enlarged faculty may bring the institution up to the State standard.

Dr. Charles E. Simpson has recently resigned as superintendent of the Lowell Hospital, Lowell, Mass., after twenty-five years of continuous service.

Antispitting Ordinance.—Spokane, Wash., has started a crusade against the spitters on the streets and in public places, and the sanitary inspectors have orders to arrest all violators of the antispitting ordinance. The health officer will ask for jail sentences for all those convicted of the offense.

Italian Cholera Deaths.—During the last week of September there were 450 cases of cholera in Italy with 116 deaths. In Rome the disease appeared among the inmates of an insane asylum, causing 44 cases and 12 deaths.

Dr. Herbert Fox has been appointed director of the Pepper Institute of Clinical Medicine in the University of Pennsylvania.

The Friends' Asylum for the Insane, at Frankford, Philadelphia, opened on October 12 a new building for hydrotherapeutic applications and other treatment. The structure is two stories high and contains on the first floor a general hydrotherapy room, with needle and shower bath, shampoo bath, and other apparatus for the treatment of violent patients. On the second floor is an operating room, with sterilizing and lighting arrangements. Here also are a leucandescent lamp, a static machine, and a vibrating machine, as well as a rest room.

New Reformatory Rules.—Beginning with the first of October, 1911, the New York State Reformatory at Elmira has declined to receive any prisoner suffering from a contagious disease, and also to accept any prisoner unless he has had a culture taken from his throat and has a certificate showing that the culture was non-infectious and free from the Klebs-Loeffler bacillus. This action has been taken as the result of an investigation into the causes of the frequent epidemics of diphtheria in the institution. Since the first of November, 1910, cultures have been taken from the throats of all new arrivals, and more than 80 cases of diphtheria were found in 1920 examinations. This constant stream of infection was a menace to the health of the inmates of the reformatory, and on the advice of the Attorney-General of the State, and at the request of the Board of Managers, the State Commissioner of Health has promulgated an order requiring the examination of prisoners before they are transferred to the reformatory. Culture outfits can be procured from the State Board of Health, and the State Laboratory at Albany will make prompt examinations and reports on specimens sent there.

Sale of Infected Meat.—The charge that the meat of tuberculous cattle is being put on the market for sale in New Jersey is made by the Chief of the Chemical Bureau of the New Jersey State Board of Health. The proper State inspection of animals, he declares, is impossible with the present force, and the result is that many infected animals are imported and later slaughtered.

The New Jersey State Pediatric Society.—A Symposium under the auspices of The New Jersey State Pediatric Society on "The Welfare of Young Children from the Educational Standpoint," will be held in the ball room of the Laurel House, Lakewood, N. J., on Saturday, October 28, at 8.30 P. M. This will be a general meeting to which all physicians, clergymen, teachers, and others interested in child welfare are invited. The following papers will be read: "The School and the Doctor," by Dr. Henry E. Jenkins, District Superintendent of Schools of the City of New York; "The Home Schools for Infants at Rome," by Prof. Howard C. Warren, Princeton University; "The Care and Training of Feeble-Minded Children," by Mr. E. R. Johnstone, Superintendent New Jersey Training School for Feeble-Minded Girls and Boys, Vineland, N. J.; "What New Jersey Is Doing for the Epileptic," by Dr. David F. Weeks, Superintendent New Jersey State Village for Epileptics, Skillman, N. J. Arrangements have been made whereby members or others who plan to attend this meeting may obtain week-end accommodations at either The Laurel House or The Lakewood Country Club. The president of the Society is Dr. Henry L. Coit; the secretary, Dr. Martin J. Synnott of Montclair.

The Medical Society of Pennsylvania.—At the sixty-first annual meeting of this society, held at Harrisburg September 25-28, 1911, the following officers were elected for the ensuing year: *President,* Dr. James Tyson, Philadelphia; *First Vice-President,* Dr. Hugh Hamilton, Dauphin Co.; *Second Vice-President,* Dr. Walter Lathrop, Luzerne Co.; *Third Vice-President,* Dr. George W. Kehl, Berks Co.; *Fourth Vice-President,* Dr. Howard C. Frontz, Huntingdon Co.; *Secretary,* Dr. Cyrus Lee Stevens, Athens; *Treasurer,* Dr. G. W. Wagoner, Johnstown; *Delegates to the American Medical Association,* Dr. G. W. Guthrie, Wilkes-Barre; M. H. Fussell, Philadelphia; T. B. Appel, Lancaster; John B. Lowman, Johnstown, and L. B. Kline, Catawissa.

The Homeopathic Medical Society of the State of New York held its annual dinner at the Hotel Savoy, New York City, on October 11. Addresses were made by Dr. E. Rodney Fiske of Brooklyn, who spoke on "The Family Doctor," and by Dr. Augustus S. Downing, Assistant Commissioner of Education in the State Department, whose subject was "Progress in Medical Education."

Minnesota State Medical Association.—At the annual meeting held in St. Paul on October 6 and 7 the following officers were elected for the ensuing year: *President,* Dr. Haldor Sneve of St. Paul; *First Vice-President,* Dr. O. T. Sherping of Fergus Falls; *Second Vice-President,* Dr. W. F. Wilson of Lake City; *Secretary,* Dr. Thomas McDavitt of St. Paul; *Treasurer,* Dr. R. J. Hill of Minneapolis. The 1912 meeting of the society will be held in Detroit.

Southern Homeopathic Medical Association.—The following officers were elected at the annual meeting held in St. Louis, Mo., recently: *President,* Dr. F. A. Reed of Eustis, Florida; *Vice-Presidents,* Dr. A. H. Schott of St. Louis, and Dr. H. Schwartz of St. Louis; *Secretary,* Dr. Lee Norman of Louisville, Ky.; *Treasurer,* Dr. H. Warren Johnson of Knoxville, Tenn. The next meeting will be held in Richmond, Va.

Lexington County (South Carolina) Medical Society.—At the regular meeting of the society held in Lexington on October 2, the following officers were elected: *President,* Dr. Frank G. Roberts of Lexington; *Vice-President,* Dr. James P. Drafts of Barr; *Secretary-Treasurer,* Dr. J. J. Wingard of Lexington.

Thurber Medical Association.—The annual meeting of this society was held at Milford, Mass., on October 5, when officers for the year were elected as follows: *President,* Dr. Francis H. Lally of Milford; *Vice-President,* Dr. J. W. Ledbury of Uxbridge; *Secretary,* Dr. A. J. Gallison of Franklin; *Treasurer,* Dr. C. B. Hussey of Franklin.

American Society of Sanitary and Moral Prophylaxis.— A joint meeting of this society with the New York Association of Biology Teachers was held at the New York Academy of Medicine, Thursday, October 12, at 8.30 P. M. The general subject for discussion was: "The Teaching of Sex in the Schools and Colleges." Papers were

read by Dr. G. Stanley Hall, Prof. M. A. Bigelow, and Rev. Josiah Strong.

Tri-State Medical Society.—At the annual session in Fort Madison, Ia., on September 27 the following officers were elected for the ensuing year: *President,* Dr. J. R. Christie of Quincy, Ill.; *Vice-President for Iowa,* Dr. C. P. Frantz of Burlington; *for Missouri,* Dr. J. J. Link of St. Louis; *for Illinois,* Dr. H. H. Fletcher of Winchester; *Secretary,* Dr. E. Liddleton of Pontiac, Ill.; *Treasurer,* Dr. Emery Lanphear of St. Louis. Jacksonville, Ill., was chosen as the place for the next meeting.

American Association of Obstetricians and Gynecologists.—The twenty-fourth annual convention was held in Louisville, Ky., on September 26 and 27. The election of officers resulted as follows: *President,* Dr. X. O. Werder of Pittsburgh; *Vice-Presidents,* Dr. Louis Frank of Louisville, and Dr. M. A. Tate of Cincinnati; *Secretary,* Dr. E. G. Zinke of Cincinnati. The next meeting will be held in Toledo, Ohio, on the third Wednesday in September, 1912.

Obituary Notes.—Dr. William Bertram, a retired physician of Keokuk, Ia., who was graduated from the University of Berlin, Germany, in 1849, died at his home on October 3, aged 85 years.

Dr. Jerome Bruce of Sanford, Fla., a graduate of the Jefferson Medical College of Philadelphia in 1856, died at his home on September 28, aged 75 years.

Dr. Walter H. Peters of Lafayette, Ind., a graduate of the Medical College of Ohio, Cincinnati, in 1886, and a member of the American Medical Association, the Indiana State and Tippecanoe County Medical Societies, and the Academy of Ophthalmology and Oto-Laryngology, died at his home after a long illness on September 28, aged 52 years.

Dr. John Titus Hay, superintendent of the Nebraska Hospital for the Insane, Lincoln, Neb., a graduate of the Medical Department of New York University in 1878, and a member of the American Medical Association and the Nebraska State and Lancaster County Medical Societies, died at his home after a short illness on September 29.

Dr. Henry Gibbons, Jr., Dean of the Cooper Medical College, San Francisco, died at his home after a short illness on September 27, aged 71 years. Dr. Gibbons was graduated from the Medical Department of the University of the Pacific, San Francisco, in 1863, and in 1870 was elected dean of the college, becoming professor of obstetrics and the diseases of women and children in 1882. From 1870 to 1873 he served as health officer of San Francisco, and was a member of the San Francisco Board of Health from 1880 to 1883, and of the Board of Education from 1889 to 1891. He was a member of the American Medical Association, the American Association of Obstetricians and Gynecologists, and the California State and San Francisco County Medical Societies.

Dr. Charles C. Sage of Monroe, La., a graduate of the medical department of the Tulane University of Louisiana in 1861, died at his home on September 26, aged 79 years.

Dr. Hermann Kiefer of Detroit, Mich., a graduate of the University of Heidelberg, Germany, in 1849, a member of the American Medical Association and of the Michigan State and Wayne County Medical Societies, and a former regent of the University of Minnesota, died in Grace Hospital, Detroit, on October 11, aged 86 years.

Correspondence.

PHOTOMICROGRAPHS IN NATURAL COLORS.

To the Editor of the Medical Record:

Sir:—In your issue of October 7, 1911, is a paragraph entitled "Photomicrographs in Natural Colors," which concludes with this statement: "The high cost, the great amount of time required, and the large number of failures in proportion to the number of successful plates secured seem to account for the present commercial insignificance of color photography."

In my "Handbook of Physiology," Macmillan, 1905, is an atlas of sixteen colored plates. Plates II, IV, V, VII, IX, X, XV, and XVI are photomicrographs in natural colors, printed on an ordinary press at an expense but little greater than that of ordinary process plates. These were prepared from negatives of stained histological specimens, taken through two or three color-filters by Dr. Edward Leaming. The color plates were made through a transparent screen with a ruling of 175 lines to the inch. The etching was done in comparison with the actual objects, which were used as color guides. The printing was done in the same way as in ordinary three-color work. To quote from the preface: "The cost of the three-color work has made but an insignificant addition to the price of the book, while, it is believed, the color illustrations have added greatly to its practical value."

The eight plates taken from actual histological preparations contain six figures each, in all, forty-eight figures. While the initial labor in the preparation of these plates was considerable and the early disappointments many, the direction given for the work, it was hoped, is such that little trouble would be experienced by any who might follow. Our greatest disappointment is in the fact that the production of these illustrations has not been noticed by those who, we hoped, would be interested in such work.

WASP-STINGS AND INFLUENZA.

To the Editor of the Medical Record:

Sir:—A patient fifty-four years of age is accustomed to being stung by wasps without much disturbance beyond the use of expletives and local pain lasting for a few minutes. Recently he suffered from an acute attack of influenza with profuse watery discharge from the nose, dusky red fauces, loss of appetite, and general malaise. On the third day of this attack he was stung on the leg by a yellow jacket (*Vespa arenaria*).

The site of the sting became excessively painful and swollen, with extensive serous infiltration in the tissues from the knee to the ankle. An hour later the symptoms of influenza subsided rapidly, and three hours later the patient felt perfectly well, with a hearty appetite for his dinner. This relief from the influenza continued for two days, during the time when reaction from the sting of the wasp was most intense. On the subsidence of the inflammation of the leg on the third day symptoms of influenza again reappeared, and while not as marked as previously, persisted for a fortnight.

We know that bee-stings have been used for the cure of rheumatism, and in some parts of the coun-

try bee-keepers receive a fee from rheumatic patients for systematic application of bee-stings. This rather crude method of treatment has never received much recognition on the part of the profession, and I have been skeptical of the actual importance of such treatment, but the observation of the effect of a wasp-sting in the case quoted would suggest that the severe local reaction and the general effect from so slight an amount of poison as that introduced by a single yellow jacket brings up a subject worthy of really serious consideration.

NEW YORK.

FLUID EXTRACT OF THYROIDS IN EPILEPSY.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—About six weeks ago I administered a fluid extract of sheep's thyroids to a young lady suffering since childhood from both petit and grand mal, attacks occurring almost daily, with all the constitutional consequences. This therapeutic endeavor was based upon the fact that the thyroid extract, by its action on the vasoconstrictors, equalizes the blood distribution. A very beneficial effect appeared in a couple of weeks, but then the necessity developed to support it by a tonic for the heart. For this was selected, following Bechterew tincture of adonis vernalis, and with an occasional, at first, dose of the bromide of sodium the attacks subsided to a very light one once a week. The last two weeks there was only one very light one, brought on by fright. Iron, in the shape of Blaud's pill, could be added with improvement in digestion. The formerly almost helpless young woman now assists her mother in the household, but she is not yet allowed to come to the office for an additional electric treatment. Encouraged by this result, I have taken two other young women under treatment; one three weeks ago with already very great reduction of the number and severity of the attacks; the second one, but one week ago, feels better, too. The formula which I use is fluid extract of thyroid in from 2 to 2½ drams, tincture of adonis vernalis 10 drops, distilled water to make 4 ounces; one teaspoonful in water three times a day. The publication of these cases may seem premature, but the object may pardon this.

NEW YORK.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

LORD MAYOR A DOCTOR—HOSPITALS ASSOCIATION CONFERENCE—OPENING OF SCHOOLS—COST OF HOSPITALS—COLOR BLINDNESS—MEDICAL CURIOS FOR EXHIBITION—CEYLON'S OFFER TO TROPICAL SOCIETY—JOINT TUBERCULOSIS IN SANATORIUM—THE BRITISH PHARMACOPŒIA—OBITUARY.

LONDON, September 29, 1911.

TO-DAY Sir Thomas B. Crosby, M.D., F.R.C.S., England, who is also a justice of the peace and alderman for the city, has been elected Lord Mayor of London, with all the old-world ceremonial. I believe this is the first occasion on which a medical man has occupied that position, and I rather think he is the oldest gentleman who has filled the chair, for he is over eighty years of age. For some thirty years he has devoted himself largely to city work. In 1898 he was elected alderman. In 1906-7 he was sheriff and that year was knighted. He practised for many years in the city. He has been president of the Hunterian Society, and his oration (1871) was published under the title "Modern Medicine." He has received a number of foreign honors, as the French Legion of Honor, the Russian Order of the Crown, the St. Olaf of Norway, Danebrog of Denmark, and the Rising Sun of Japan.

Yesterday the British Hospitals Association opened its second annual conference at Manchester and Sir William Cobbett, chairman of the Royal Infirmary, presided. He spoke of the probable effect of the insurance bill on voluntary hospitals which must, he held, divert two of the sources of income. It taxed both workers and their employers, and they would cease to subscribe. Mr. Lloyd George pretended to think better of human nature than that, but advanced no argument to meet the experience of those who administered hospitals. To jeopardize them was not statesmanlike. The sympathies of the meeting were with the chairman, who suggested that insured persons who became in-patients should be paid for. Dr. Mackintosh of Glasgow would make the health committees defray the cost of hospital treatment for their members, and Mr. Lupton of Leeds said if subscriptions fell the burden would be laid on the municipalities. Dr. J. E. Smith of the Children's Hospital of Bristol saw the time approaching when hospitals must be state aided. Sir H. Burdett said the scheme was being pushed too hastily, and Mr. Lloyd George should be told that in its present form it would be the death of the voluntary hospitals which were admired throughout the world. To abolish that system would be a bitter wrong. They asked for no doles but were willing to take state patients on business terms. Scarcely a doubtful speaker intervened, and the conference passed to consider the question of the several societies which are more and more dissatisfied.

Monday next is "our opening day" at the medical schools. It is celebrated in a very different manner from former times. As you know, several schools have for some years given up the time-honored introductory lecture, but will in some way or other keep up the opening. Even at Old Bart's, which has abandoned all formal ceremony, the old students gather at a dinner in the great hall of the hospital, under the presidency of the senior ophthalmic surgeon, Mr. Jessop. A dinner is also fixed for most of the other hospitals; in some a conversazione is arranged for additionally; in some a prize-giving; in some an address, which may partake more or less of the introductory.

The cost of hospitals is a pretty constant subject of discussion, and the necessity of economy is impressed on administrators from various sources. A real contribution to the facts has been made in a report for 1910 issued by the honorable secretary of King Edward's hospital fund. Since such reports have been published many economies have been effected, and a comparison between 1910 and 1909 shows a continuance of reductions in expenditure. It is pointed out these reductions cannot be on the same scale as those which followed the first reports. In 1905 they were reckoned in the case of sixteen hospitals at £21,000 per annum: in 1906, with forty-eight hospitals, at an additional £18,000 per annum. Then came a period when exact comparison was not possible because a change in the system of keeping the accounts was being made. The first comparable years under the new system were 1908 and 1909, and they show a further saving

of £6,000 in fifty-five hospitals. Last year a further decrease, as stated above, is reported. The new report gives a mass of statistics of expenditure in various depatrments comprising total cost, cost per bed, per out-patient's attendance, and of controllable items, year by year, in London hospitals, which number 106. These are sixteen general, which averaged over one hundred beds in daily occupation during the year, fifteen with under one hundred, four consumption hospitals, five ophthalmic, five for women, seven for children, three for epilepsy and paralysis, twelve cottage, eight lying-in, and thirty-one unclassified. The total number of beds available was 9,949; the average number in daily occupation, 8,447. The total number of out-patients was 1,515,194.

Color blindness is so obvious a danger in certain employments, as signalers or seamen, that it is strange precautions are not more constantly and thoroughly taken by those responsible for their employment. Stranger still is it that some persons continue to deny that accidents have been caused by the mistakes of color-blind persons. Our leading authority on the subject, Dr. Edridge-Green, Hunterian professor at the Royal College of Surgeons, has consequently contributed to the current *Lancet* a number of instances collected from various publications in which fatal mistakes have been made and others in which there have been narrow escapes. Two of the latter are especially convincing, as the accidents were only prevented by the prompt intervention of the captain of the ship. Color-blindness in a navigating officer is a natural explanation of many a mysterious shipwreck. Dr. Edridge Green has long ago shown the inadequacy of the Board of Trade tests and supplied a reliable method which ought to be substituted.

Sir F. Champneys, Bart, is chairman of a committee to organize a medical department of the missionary exhibition which is to be held next June. Many doctors, travelers, missionaries, and others are possessors of medical curios from other lands and the committee would be grateful for the loan of such articles during the exhibition. They promise to take the greatest care of them and to return them immediately after the exhibition.

The School of Tropical Medicine here has received an offer from the Ceylon government of £750 for an investigation of sprue. It is probable this offer will be accepted and an able worker will go to Ceylon to begin a research, which I suppose will extend to other countries where the disease is met with. It is hoped that an additional sum of at least £250 will be given by the Ceylon Tea Planters' Association.

Dr. Duncan Forbes reports that the experiment of treating tuberculosis of joints and bones in the Brighton Sanatorium has been successful. Two hip cases have been cured without deformity but one of the knee was not improved. Nine cases are under treatment, four of spine and five of hip. One of each will be discharged as cured in a few days. The Brighton town council has authorized the experiment to be continued for another year.

The new edition of the British Pharmacopœia is to be edited by Dr. Tirard and Professor Greenish.

Dr. Surgeon-General Charles Kelway Colston of the Indian Medical Service, retired, died September 21, in his seventy-ninth year.

Mr. James Reid, F.R.C.S., consulting surgeon to the Canterbury Hospital and for some time surgeon to H. M. Prison, died September 12.

The Frequency of Venereal Diseases. A Reply to Dr. Cabot. P. A. Morrow.
A Reminiscence of My Professional Life. D. W. Cheever.
Prognosis in Infantile Paralysis. B. E. Wood.

Salvarsan.—H. P. Towle states that this drug is still under fire and that physicians are still in doubt as to many of the facts concerning it.

Parasitology of Syphilis.—H. C. Ernest notes that *Treponema pallidum* being placed in a new genus and removed from among the spirochetes, the relationship between it and the trypanosomes has become less probable than before.

Chemistry of Salvarsan.—W. F. Boos discusses this subject with the aid of a series of graphic formulæ. He states that salvarsan is very stable and acts as such rather than through decomposition products. That is why relatively much greater quantities of arsenic may be given in form of salvarsan than as cacodylate of sodium or atoxyl. A considerable part of the dose injected is probably bound immediately by the liver, which then permits a small quantity at a time only to pass into the circulation on its way to excretion. In this way long-continued action is insured.

The Preparation of Salvarsan for Injection.—J. Godsoe describes the technique of the preparation of salvarsan for injection.

Clinical Observation on Salvarsan.—H. Cabot suggests that some modification of the intramuscular method which will remove or mitigate the pain is likely to become the method of election. He still clings to the view that the production of a profound effect upon the disease is desirable and that the use of repeated small intravenous injections is less likely to produce this effect. In the light of present knowledge the author believes that one may safely affirm that the drug is a valuable addition to our means of treating syphilis, but it has yet to be shown that it will revolutionize our practice.

The Value of Salvarsan.—S. Pollitzer concludes that salvarsan is the most effective drug we possess for the symptomatic cure of the active lesions of the disease; that its best effect is produced by an intravenous followed by an intramuscular injection; that while one or two injections are not likely to cure the disease they will materially advance its cure; that its use, together with treatment by mercury or sometimes by iodides, will bring about a negative Wassermann reaction far more certainly and more quickly than is possible with mercury alone; that properly used it is practically harmless even in repeated doses.

Personal Experience with Salvarsan.—A. Post points out that there is a certain analogy between mercury and salvarsan. Both of them are toxic; with both we get apparent cures; with both we get recurrences. Salvarsan acts more quickly. It gives one apparent cures in cases in which mercury has failed; but one finds occasionally cases in which the real value of salvarsan is doubtful.

The Frequency of Venereal Diseases.—P. A. Morrow criticises the observations recently made by R. Cabot, relative to the frequency of venereal diseases, based upon hospital investigation. It is laid down as a general proposition that the statistics of general hospitals as to the actual or relative frequency of venereal morbidity are worthless. In concluding his article the author states that venereal diseases, viewed in their triple significance as a danger to the public health, a peril to the family, and a

menace to the vitality, health, and physical progress of the race, are the greatest of modern plagues, and that the prophylaxis of these diseases is the most pressing problem of preventive medicine that confronts one at the present day.

Reminiscences of Professional Life.—D. W. Cheever, among other things, discusses the modern eclipse of the general practitioner and the rise of the specialist. He states that the single doctor, the general practitioner, the family doctor, to use convertible terms, was a pastor, a mental healer, a refuge of last appeal, a father confessor, as well as a medical curer or caretaker. By long familiarity he knew the body and the mind of the patient, his tendencies, his inheritances, his constitution. Specialists, with occasional calls and limited fields of vision, do not respond to these needs. More might be said of the inestimable advantage of overseeing the whole body, and not a part. There can be no isolation of functions.

Prognosis in Infantile Paralysis.—B. E. Wood states that in anterior poliomyelitis complete recovery or functional recovery occurs in something over 25 per cent. of cases examined at the end of four years. Atrophy may exist without impairment of function. In about half of the author's recovered cases the onset was mild. The distribution of the paralysis in such recovered cases was not essentially different from that in cases which do not recover. Recovery in many instances required months, and in several cases from one to three years.

The Nauheim Treatment.—By J. M. Swan. (See MEDICAL RECORD, September 30, 1911, page 695.)

Carcinoma of the Stomach.—J. F. Erdmann states that a palpable or even a palpably non-movable tumor of the stomach is not an inoperable entity. Analyses of symptoms and stomach contents are at present at fault for perfect diagnosis, so that early exploration is necessary in cases whose train of symptoms causes more than a suspicion of carcinoma of the stomach. Due weight should be given to the possibility of carcinoma being present in the patient who complains of some stomach difficulty for years, or who gives a clear history of having had ulcer of the stomach some years previously, as this disease is more than a factor in the history of carcinoma; to the time of pain in its relationship to food intake, and to the question of vomiting and its character—whether it, the vomitus, contains food of one or more meals back, *i.e.* retention or cumulative vomiting. Due weight should also be given to emesis containing blood in various stages; to blood in the stool; to loss of weight; to rapid diminution in hemoglobin, to prostration, etc.

X-Ray Diagnosis of Ulcer of the Stomach and Duodenum.—By H. Adler and H. E. Ashbury. (See MEDICAL RECORD, vol. 79, page 1024.)

Fatal Vasomotor Gangrene.—R. N. Willson reports the case of a man aged fifty-three years, in whom there were a long continued cyanosis and a gradually developing gangrene of the extremities and of the nose. The cold extremities became warm, and the natural color returned as though the causal influence had momentarily been set aside. The opportunity was afforded of obtaining by dissection the arteries leading into and supplying the gangrenous extremities. In no instance could either obliteration or thrombotic process be discovered. As is often the case, the anterior tibial and the posterior tibial were small, and the dorsalis pedis spread out into a fan-shaped division of tiny vessels supplying the dorsum of the foot. Nowhere was the arterial tree obstructed, however, and nowhere was there an explanation afforded for the gangrenous process other than the supposition that the case was one of Raynaud's disease, and that the active cause of the gangrene was to be found in a peripheral vasomotor constriction, with consequent starvation and gangrenous degeneration of the extremities and of the tip of the nose.

Music in Therapeutics.—J. Knott continues his article on this subject.

Writer's Cramp.—T. A. Williams reports the case of a naval paymaster, aged thirty-two years, who after recovery from an operation for perityphlitis found that his signature was no longer uniform, was exceedingly shaky, and was made with increasing difficulty as the day progressed. In explaining the pathogenesis of this condition, the author states that the patient's attempt to resume work, necessitating long continued writing, before he was in a proper state to do so, led to a tremulousness of the hand and arm similar to that which ensues upon excessive consumption of coffee or tobacco or is caused by the toxin of some infectious or fatigue condition. The treatment consisted in explaining to the patient that the fear of making an improper stroke caused lack of freedom and cramping of the muscles. He was directed to make free arm movements with chalk on the blackboard, paying no attention to the forms he drew, then to pass to a slate and later to pencil and paper, and then to gradually reduce the size of the writing. After performing these exercises for one month the patient recovered.

Psoriasis.—F. C. Curtis discusses the indications for treatment in this disease. A person who is anemic, debilitated, neurotic, rheumatic, plethoric, overfed, indifferent to his elimination, and sedentary in his habits needs the treatment appropriate for himself, not for his psoriasis.

Achroodextrin in Stomach Contents.—H. Weinstein describes his method of determining by means of a 1 per cent. alcoholic solution of iodine the amount of achroodextrin in the stomach contents. This method he calls the "achroodextrin saturation test." He notes that achroodextrin and erythrodextrin are both frequently found in hyperchlorhydria, and amylodextrin may be absent. In normal secretion there may be no erythrodextrin, but small quantities of achroodextrin and a preponderance of amidulin may be found. Even in subacidity there may be no erythrodextrin, while achroodextrin and amidulin may both be present. All the dextrins may frequently be demonstrated in the filtrate, irrespective of the secretory condition, excepting anacidity. Achroodextrin and maltose are almost always present in the filtrate.

Eosinophile Cells and Pollen in Vernal Catarrh. B. Pusey.
An Arthroplastic Operation for Hammer-Hoe. By J. O'Neill.

Resection of the Posterior Roots of the Spinal Cord.—W. A. Jones concludes that old and new chartings of sensory areas are variable and unreliable. Each individual, according to circumstances, has an individual center for pain. The segments in the spinal cord follow no defi-

nite order except when gross lesions are present, and even here one may be in error. When the posterior roots are sectioned for pain, it may be necessary to divide more than three, perhaps as many as five, roots to accomplish relief. In some instances it is advisable to section one-half of several roots, or alternate roots, to abolish or diminish pain and spasm. If this order is followed, there is less likelihood of disagreeable results, such as helplessness from greater or less loss of voluntary control. One should allow the patient to come out of the anesthetic and should reopen the wound for further root section, in case pain persists.

Pathological Findings in Hypertension.—By R. I. Lee. (See MEDICAL RECORD, July 8, 1911, page 93.)

Reserve Renal Capacity in Nephritis.—By E. F. Wells. (See MEDICAL RECORD, July 8, 1911, page 93.)

Treatment of Diabetes Mellitus.—A. J. Hodgson states that the following points are essential to the successful treatment of diabetes mellitus: (1) To impress on the patient that after his apparent recovery continued care in eating is essential to continued health. (2) To dispense, as a general thing, with such drugs as codeine and arsenic and to make the patient rely practically entirely on the diet and hygiene. (3) To insist on the restriction of the quantity of food just as much as on the kind. (4) To overcome constipation by the use of castor oil and olive oil or by the use of a mixture of these two with glycerin. (5)To insist that the food must be thoroughly masticated. (6) To restrict carbohydrates at the outset to the smallest possible amount consistent with safety. (7) To add starches gradually in but one form rather than in several until the point of tolerance has been reached. (8) To eliminate from the dietary those articles of food that have been found to be difficult of digestion, even in health, though their starch-content may not be objectionable for a diabetic. (9) Above all, to impress the patient with the fact that his disease is essentially the result of vicious dietetic habits and that it is useless for him to expect any favorable results so long as the habit is persisted in.

Detection and Estimation of Glucose in Urine.—By S. R. Benedict. (See page 839.)

Ethical Proprietary Preparations.—M. H. Fussell objects to the use of these preparations without an exact knowledge of their composition and action.

Abnormal Heart Rhythm.—A. Schurman notes the following points: A disturbance of cardiac rhythm does not in itself indicate a bad prognosis. A disturbance of cardiac rhythm in itself is no indication for the institution of treatment directed to the heart. It is necessary to analyze a cardiac irregularity, so as to determine which of the types is present, for the prognosis and treatment depend on the type of disturbance. One should not rush to digitalis as soon as a pulse irregularity is discovered, for in most of the types this drug is contraindicated. When auricular fibrillation accompanies symptoms of cardiac failure digitalis is the drug strongly indicated.

Serofibrinous Pleurisy and Empyema.—By J. M. Anders and A. C. Morgan. (See MEDICAL RECORD, July 8, 1911, page 94.)

Eosinophile Cells and Pollen in Vernal Catarrh.—B. Pusey, having noted many points of similarity between vernal catarrh and the conjunctivitis of hay-fever, has been led to the examination of smears taken from a series of cases of the latter disease. In smears taken from the conjunctivæ of a series of cases of hay-fever he has found eosinophile polymorphonuclear leucocytes in great abundance; indeed the cellular content of a smear from the one disease is the same as that from the other. This observation shows another, and possibly a very important, similarity between the two diseases. It is known that the conjunctivitis of hay-fever is due to pollen. The author believes that the presence of eosinophile cells in the conjunctivitis of hay-fever and in vernal catarrh and their absence in ordinary forms of conjunctivitis point strongly to a similar etiological factor—pollen.

Hammer-Toe.—B. J. O'Neill reports a case in which Murphy's arthroplastic operation was applied in the treatmen of this condition.

Some Clinical Observations Upon Septic Infections of the Hands and Fingers. C. A. Pannett.
A Case of Congenital Atresia of the Duodenum. W. F. Roe and E. H. Shaw.

The Possible Toxic Origin of Some Kinds of Insanity.—E. Goodall believes that there are no adequate grounds for believing that the organisms which have been found in the tissues in any case of insanity play more than a secondary rôle. The outstanding pathological fact which indicates a toxic pathogenesis for some of the psychoses is leucocytosis. The condition is found very commonly in acute and recent mental disorder, and in states of exacerbation during chronic insanity. As a generalization, in the acute and recent mental disorders there is leucocytosis with percentage increase of the polynuclear cells; in the subacute and chronic ones there is little or none, and the proportion of large mononuclears and lymphocytes is increased. In acute mental disorders absence of leucocytosis and a fall in the percentage proportion of polymorphs go with deficient reaction, and are an unfavorable indication, as is the case in those infectious fevers in which leucocytosis is observed. This, from the standpoint of toxemia, is significant.

Surgical Treatment of Epilepsy.—W. Alexander concludes that there are some cases of epilepsy that prove intractable to general medical and hygienic treatment, and these, unless the disease be somehow arrested, will soon terminate in imbecility and death. In these cases the affected motor area is covered by more or less edema of the pia-arachnoid, and this edema probably so affects the cells of the cortex as to predispose to, or cause, the epilepsy and imbecility. In cases with localizing aura, one can, by the operation of fenestration of the dura mater, drain these edematous areas and prevent reaccumulations. By the operation the progress of the disease has always been retarded. In several the fits have stopped, and in many have been reduced to fractions of the original number.

Viability of Human Carcinoma in Animals.—C. L. Williams found that portions of human carcinoma implanted into animals were observed during the first five days to retain their vitality and to exhibit mitosis after implantation. After the expiration of this period no evidence of vitality was observed. Mitosis was markedly inhibited within twenty-four hours of implantation, while the life of the implanted cells was abolished less rapidly.

Salvarsan, Mercury, and Potassium Iodide.—J. McIntosh and P. Fildes compare the curative efficacy of these substances in experimental syphilis in the rabbit and conclude that salvarsan possesses spirocheticidal properties much in advance of mercury, and that potassium iodide is not a direct antisyphilitic.

Intussusception of the Appendix.—J. H. Watson reports a case of this condition.

Foreign Bodies in the Appendix.—L. A. Bidwell states that a foreign body has been found in about 20 per cent. of the appendices which he has removed. The interesting point is that a foreign body by itself sets up

very little irritation, and does not produce acute inflammation; it is only when a fecal concretion forms around it that acute appendicitis will occur. According to many authorities no foreign body or fecal matter can enter a healthy appendix, and it is stated that some previous inflammation must occur in order to make it possible for the body to enter. If this is the case, a foreign body by itself could not have very much influence in producing appendicular disease. It is, however, more reasonable to suppose that the irritation of the foreign body excites an extra secretion of mucus, which is deposited upon the body, producing the concretion, and so becomes the starting point of an attack of appendicitis.

Erysipelas and Meningitis Following an Intranasal Operation.—L. A. Parry reports a case of extensive erysipelas of the pharynx, face, and scalp following an operation of submucous resection of the nasal septum in a man aged 27 years. The erysipelas cleared up but was followed by a severe meningitis, which was combated with a polyvalent antistreptococcus serum. Recovery ensued.

Septic Infections of the Hands and Fingers.—C. A. Pannett presents a series of clinical observations on this subject. In affections of the fingers the pus may be subcuticular or subungual, subcutaneous, thecal, or subperiosteal. Subcutaneous whitlows are the commonest met with in the fingers—much commoner than thecal whitlows. Infection of the tendon sheaths can usually be easily diagnosed before incision. In the case of the subcutaneous whitlow flexion and extension, to some extent at least, are usually possible without great pain. In a thecal panaritium there are extreme tenderness and pain, often localized to one point, and any attempt at extension or flexion of the finger markedly aggravates the suffering. The finger is held rigidly flexed. The synovial sheaths in connection with the tendons of the little finger and the thumb extend upward and are continuous with the great anterior carpal synovial sac. Yet involvement of this sac in a thecal panaritium of the thumb or little finger is not common. The subperiosteal whitlow is most commonly seen in the case of the terminal phalanges. Another result of deep infections of the finger is a septic arthritis of one of the joints.

Congenital Atresia of the Duodenum.—W. F. Roe and E. H. Shaw report a case of this condition.

Treatment of Antepartum Hemorrhage. G. E. Herman.
Malformations of the Female Genital Organs in Their Clinical Aspects. A. E. Giles.
The Inefficiency of the Present Methods of Saline Infusion. A Description of a New Method. N. S. Carruthers.
Painless Swellings of the Parotid Secondary to Local Sepsis. C. E. L. Burman.

Antepartum Hemorrhage.—G. Ernest Herman states that accidental hemorrhage, slight in amount, is not uncommon, and seldom dangerous. Concealed accidental hemorrhage is a very dangerous thing and is rare. Plugging the vagina is bad treatment. Practically it is illusory, for it only prevents the escape of blood for a little while. Theoretically it is unsound, for if it did prevent the escape of the blood from the uterus it would only convert the case into one of concealed hemorrhage, which is the most dangerous form. The best treatment for the majority of cases is to rupture the membranes. This acts instantly, lessens the tension within the uterus, and stimulates the uterus to contract. Before doing this, care should be taken that the long axis of the child coincides with the long axis of the uterus, and, if possible, that the head presents. If the patient has lost so much blood that it seems likely that the inevitable hemorrhage of the third stage of labor will be fatal, the best treatment will be amputation of the body of the uterus, after preliminary ligature of the vessels. In placenta previa as soon as the diagnosis is made premature labor should be induced. The placenta should be separated with the finger, the membranes ruptured, and the child's foot brought down. The hemorrhage can be controlled by pulling on the child's leg. In a lying-in hospital the dilation of the cervix can be hastened by the insertion of a Champreties de Ribes' bag. The author does not favor cesarean section in the treatment of placenta previa.

Malformations of the Female Genital Organs.—A. E. Giles discusses these in their clinical aspects and reports illustrative cases. The first group includes malformations leading to confusion of sex. Example: a case of androgyny, the patient living as a married woman. These are cases of pseudohermaphroditism. The second group includes malformations that preclude or are unfavorable to childbearing, but allow menstruation and marriage. In this category are cases of underdevelopment of the uterus of minor degree. There may also be congenital retroversion of a small uterus. Another class of cases is that in which there is some malformation of the tubes, such as congenital occlusion. The third group of malformations preclude childbearing and menstruation, but not marriage. This group includes cases of infantile uterus and of normal uterus with defective ovulation. The fourth group of malformations are those that preclude marriage and childbearing but not menstruation. These are cases of stenosis of the vaginal orifice. The next group of malformations are those that preclude menstruation, marriage, and childbearing: *e.g.* atresia of or absence of the vagina. The former condition is remediable; the latter is not. The sixth group of malformations allow of menstruation, marriage, and pregnancy, but may be attended by complications. Examples are uterus unicornis, uterus septus, uterus bicornis, uterus didelphys. This group also includes cases of double uterus and vagina with atresia of one-half of the vagina.

Saline Infusion.—N. Stuart Carruthers describes a new apparatus for the subcutaneous administration of saline solution.

Painless Swelling of the Parotid.—C. E. L. Burman reports three cases of this condition secondary to local foci of sepsis: pyorrhea alveolaris, follicular tonsillitis, and mastoiditis, respectively. In each of the cases a definite cause could be assigned—namely, sepsis from neighboring parts. One would expect some pain to have been present in the parotid swelling, but this was entirely absent. In all three cases that part of the gland which lies in front of the lobe of the ear and the angle of the lower jaw showed the largest amount of inflammation. The character of the swelling did not simulate that of mumps or that due to the more severe forms of inflammation. Fever was entirely absent in all three cases, and the condition quickly subsided after treating the septic focus.

Berliner klinische Wochenschrift.

October 2, 1911.

The Salvarsan Treatment of Syphilis.—Von Zeissel has now treated 273 cases of syphilis with salvarsan and writes with especial reference to the alleged neurotropic action of the drug. He denies that such an action exists but admits that like mercury salvarsan may cause the appearance of precocious syphilitic affections of the nerves in certain predisposed individuals. The author is an enthusiast as to the curative properties of the drug. He had but one relapse of mucous patches in his 273 cases. We are accustomed to see relapses under mercurial treatment as soon as the latter is suspended.

Simulation of Albuminuria.—Hadda relates a case of the simulation of a renal disease. Such malingering is extremely rare and the author can find but three similar cases on record. The subject was a girl of 12 who had suffered from chorea, endocarditis, angina, and event-

ually with high fever, edema, and mild uremia, the urine containing blood and albumin not derived from the latter. The patient made a complete recovery from the nephritis and soon afterwards began to menstruate for the first time. At a late period without apparent cause large amounts of albumin began to appear in the urine. This was found eventually to be nothing but white of egg which had been placed there by the mother, who had been led apparently to practise deception in order to obtain money from her dead husband's unsettled estate.

Chemistry of Digitalis.—According to Kantorowisz the chief problem to-day in the chemical investigation of digitalis is to determine the amount of digitoxin. But the leaves contain another substance in much larger amounts than digitoxin. This is digitalein, a valuable cardiac glucoside. The latter is a very unstable substance, readily decomposed by enzymes. Leaves which have been in storage for long periods show on this account diminished activity. It should be necessary to determine the amount of digitalein as well as that of digitoxin, but we do not fully comprehend the nature of the former and it cannot be isolated pure or subjected to quantitative analysis. The nature of digitalin, digitoxin, and digitonin is fairly well known, each of these glucosides containing certain sugars in different combinations. In regard to digitalein, however, we only know that it contains a certain amount of dextrose.

Münchener medizinische Wochenschrift

September 26, 1911.

Idiosyncrasy to Ten Substances in a Single Patient.—Mertens discusses idiosyncrasy in general. It has been defined as a reaction to one substance or a definite group of substances. In rare instances only do we find idiosyncrasy toward several different substances. The author's case belongs to this exceptional type. The patient was a woman aged 42, who had been operated on for chronic appendicitis. It became apparent that she was intolerant to the following: iodoform, mercury, bromine, veronal, morphine, boron, zinc, and also strawberries and crabs. The phenomena present were those most commonly encountered in idiosyncrasies to the various substances and were in part local, in part systemic.

Transient Glycosuria in Phlegmonous Affections.—Becker quotes the prevalent views on sugar metabolism. The content in the blood is kept constant by an automatic mechanism. The liver stores it as glycogen and the diastatic liver enzyme changes it to dextrose, whereupon it reenters the blood as required. The mechanism is controlled by the internal secretion of the pancreas on the one hand and the adrenals on the other—the former acting as a check to the latter. The thyroid and pituitary body also act synergistically with the adrenals. But this mechanism cannot explain all the instances encountered of glycosuria of a transient character. The author cites numerous examples of the latter in connection with furuncles and other phlegmonous affections. The association is important, for when a subject is attacked with furunculosis our first thought is usually of latent diabetes, and the occurrence of phlegmonous processes in manifest diabetes is well known. It is evident that the trace of urine sugar found in connection with boils and carbuncles, which has often led to a diagnosis of diabetes, may not have proceeded from antecedent glycemia, but is a simple consequence of the phlegmonous process.

Röle of the Pig and Rat in Trichinosis.—Stäubli found that when rats were fed on trichinous pork they often escaped infection. When infected, the animal, if it lived, suffered only moderately from muscle trichinosis. If the rat died with the disease and was eaten by other rats, these were attacked with intestinal trichinosis. A systemic infection did not follow. If an infected rat was eaten by a pig, the latter usually contracted only a mild muscle trichinosis. The rat doubtless plays a minor rôle in the propagation and maintenance of the malady.

Deutsche medizinische Wochenschrift.

September 28, 1911.

Influence of Affects on the Distribution of Blood.—Citron discusses both physiological and pathological shifting of the blood from one region to another. The former is seen in blushing and pallor, the latter in various active congestions and ischemias and generally speaking in all vasomotor pathology. Various drugs, notably alcohol, cause notable changes in the distribution of blood, and the same is encountered throughout the entire domain of hydrotherapy. The subject of anomalies of blood distribution is therefore psychophysiological, and the lability of the vasomotor system in neurasthenia, Graves' disease, etc., causes it to be readily influenced by both psychic and physical factors. The author has experimented extensively with the plethysmograph upon the distribution of the blood as influenced by affects, both psychical and physical, and believes that plethysmography will have a place in practical diagnosis.

The Toxin of the Mosquito—Bruck writes of the essential chemical poison of the culex which is able to cause the formation of wheals and papules. Our knowledge of insect poisons is still crude. We know about cantharidin, bee poison, and the venom of arachnids, which latter can generate antibodies. Little is known evidently of the poison of ants, fleas, bedbugs, etc., and our knowledge of the toxic principle of wasps and hornets is largely inferential, from its probable resemblance to that of the bee. The poison of the mosquito is termed by the author culicin. It is believed to reside in the insect's saliva, and is obtained by extraction from the bodies of large numbers of the creatures, using water, glycerine, chloroform, etc. Animal experiment shows that the extracts possess hemolytic powers. The author inoculated his own skin with culicin and produced lesions which behaved exactly as do those following natural mosquito bites.

Behavior of Salvarsan in the Organism.—Stümpke and Siegfried conclude that directly after its injection a large proportion of salvarsan is deposited in the liver. This state of affairs persists for some days. Gradually the amount in the liver becomes less, but traces may be found therein for months. Other parenchymatous organs contain arsenic in much smaller amounts. Arsenic may be present in the urine even when absent in the kidneys. The occurrence in the heart and lungs of arsenic is not readily intelligible. It is never found in voluntary muscle. It occurs in the blood only for the first twenty-four hours after injection, and then in traces. Evidently as the drug is released from the liver it must circulate for a short time in the blood, yet the most delicate tests fail to reveal a trace.

Operative Cure of Cancer of the Bladder.—Riese calls attention to the rarity of relative cure of cancer of the bladder after operation. He refers to cancer which begins in the bladder proper, and which is technically operable. In 1905 he removed a growth from the bladder of an old lady. It was a papillomatous cancer. Four years later death occurred from old age and without recurrence of the tumor. In a second case of the same type the date of operation is omitted, but it is stated that recovery was permanent. A third patient of the same class remained well one year after operation.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

PERSONAL HISTORY.

NERVOUS SYSTEM.—The stress in modern methods of business and the excesses in certain classes of society, especially in the large cities, are causing a large and increasing number of cases of diseases of the nervous system, some of which are difficult to discover in the early stages and are both incurable and fatal. One of our foremost neurologists has made the statement to a medical director of one of the companies that he would guarantee to produce individuals who would be passed by the majority of the best life insurance examiners and yet who would die in three or four years. While, then, a searching inquiry should be instituted whenever the applicant admits the history of a disorder which is likely to be associated with some mental derangement or which is liable to recur or leave a permanent physical defect, the examiner should also have in mind the possibility of the existence of one of these dreaded diseases in which the premonitory signs are so insidious and obscure. Subjects of marked disease of the nervous system, when the diagnosis is comparatively easy, rarely apply for insurance except in the case of those who have had infantile paralysis and been left with some atrophy and difficulty in locomotion, a condition which does not detract from the value of a life as a rule. An examination for life insurance cannot be considered complete unless the reflexes are tested, the pupils inspected, and the tongue scrutinized for the presence of the fine tremor which indicates alcoholism or the onset of general paralysis of the insane. The actual inspection of the person of the applicant for the detection of these troubles will be taken up further on under the subject "Physical Examination."

Dizziness, Vertigo.—In reporting, give the date and cause of each attack. Most people have had some dizziness or vertigo as the result of a gastric disturbance, bilious attack, or constipation, and if it was undoubtedly due to one of those causes it may be considered of little consequence, especially if the applicant was under 40 years of age at the time. Inquiry should be made, however, as to whether there was any loss of consciousness during the attacks, and, if so, whether there was any suspicion of convulsions or one of the mild forms of epilepsy. When the individual has passed the age of 40 dizziness or vertigo should not be regarded with complacency, as it may then be an early sign of cardiac weakness, vascular changes in the brain, or nephritis.

Unconsciousness, Fainting.—Give the date, duration and cause of each attack. It may have been due to injury, shock, emotion, or some illness. In the absence of any known cause it will be safer to assume that it was the result of cardiac weakness, some vascular cerebral change or epilepsy.

Epilepsy.—Give the frequency and severity of the attacks and the date of last occurrence. A history of confirmed epilepsy will cause rejection of the applicant even after a long period of immunity from attacks, as, in addition to the danger of recurrence, there is almost always a physical and mental impairment.

Convulsions.—Give the date, severity, and cause of each attack. A history of convulsions of infancy may be overlooked if there has been no recurrence since. Under all other circumstances they must be considered a grave manifestation either of some organic lesion, as nephritis, or of some neurotoc weakness, such as hysteria, epilepsy, insanity, etc., any one of which will justify rejection of the risk.

Paralysis.—Give the date and cause of the attack and the variety of paralysis. A history of Bell's paralysis is inconsequential, although it should be recorded after a careful inquiry has convinced the examiner that the palsy was due to a peripheral neuritis and not to a central lesion. Disability, following an early anterior poliomyelitis, should be fully described, as there is no objection to the acceptance of such risks provided the locomotion is not too much interfered with and the assistance of crutches is not required. Local palsies, such as "writers' cramp," lead poisoning, traumatic local paralysis, etc., may only lead to postponement of the application, until the local causes are relieved. A history of any paralysis of cerebral origin will be regarded seriously and the risk rejected.

Apoplexy.—Any history of cerebral apoplexy leads to absolute rejection. When an applicant admits dizziness, vertigo, syncope, or unconsciousness, the examiner should keep the possibility of apoplexy in mind and institute a strict inquiry into the nature of the attack.

Insanity.—Insanity is seldom acknowledged as such by the applicant; he will usually insist that the malady was in some other form, such as neurasthenia, nervous prostration or nervous breakdown. Any history of mental derangement almost always indicates a short life, although it is true that some of the worst cases of insanity enjoy vigorous physical health. Such risks will be rejected.

Neurasthenia, Nervous Prostration.—Always give dates, duration, severity, and cause of each attack. Whenever there is a history of a nervous breakdown or of a resort to treatment for nervousness, worry, fatigue, etc., there should be a careful inquiry as to the exact nature of the attack. This history is often elicited from business and professional men. The condition known as neurasthenia or nervous prostration is often regarded too lightly, and an examiner is apt to record the bare statement of its occurrence without making further inquiry. There is a fairly wide range of possibilities in the disorder. It may be defined as a functional disturbance of the nervous system, characterized by weakness and irritability, lying between hysteria and insanity, occasionally overlapped by one or the other —more frequently the former, rarely the latter. It must be ascertained positively whether the disorder was one of "brain-fag" or cardiac irritability, or whether it was accompanied by insomnia or some form of mental derangement. It should not be forgotten that insomnia is a common symptom of neurasthenia and insanity.

Neuralgia, Neuritis.—The ordinary neuralgias, so commonly met with, need little or no comment. The history of sciatica should be given in full, for, while it is usually due to a peripheral neuritis which disappears without leaving any effect on the general constitution, it may indicate some trouble in the brain or spinal cord in rare cases. With a history of neuritis the examiner should bear in mind that this condition is often the result of alcoholism and that careful questioning, therefore, is necessary.

Delirium Tremens.—Give frequency of occurrence and date of last attack, and state whether applicant resorted to a "cure," and has been a total

abstainer since the last attack and also since taking the cure.

Tremor.—The presence of a tremor should lead to a careful inquiry as to the cause. It may be congenital and of no great importance, it may occur in nervous people excited by passing causes, it may be due to the nervousness of illiteracy, or it may be a symptom of "writers' cramp." On the other hand it may result from alcoholic excesses, paralysis agitans, or disseminated sclerosis.

Headaches.—The ordinary headaches are not worth mentioning unless they have been severe, protracted, or frequent. If they are reported the examiner should give full particulars as to frequency, severity, duration, and cause, and he should state specially whether they are due to gastrointestinal disturbances, eye-strain, migraine, overwork, etc., or whether they are due to some more serious organic lesion or functional disturbance.

Sunstroke.—Give date and full details of any sequel such as epilepsy, headache, and inability to work in the sun. The acceptance of such risks is not advisable until they have gone through at least one more summer without feeling any effects of the sun or heat.

The Diagnostic Value of the Sphygmomanometer in Examination for Life Insurance.—By J. W. Fisher, M. D. (See page 818.)

The Ocular Signs of Renal Disease.—F. A. Newman first reviews the anatomy of the retina. Consisting of epiblastic tissue only, it does not show marked inflammatory changes. Its nerve fibers converge toward the disc: small hemorrhages in the nerve fiber have therefore flame-like appearances, and exudates in the macular regions form star-shaped figures. Blood supply is from the central artery of the retina, which is an end artery, and also from vessels of the choroid; in case the former is blocked the macular region, supplied by choroidal vessels, stands out as a pink disk in contrast to the exsanguinated retina elsewhere. A cilioretinal branch is occasionally present, running from the disc to the macula; in such cases central vision is maintained even when the main retinal artery is blocked. In the normal fundus the vessel walls are not seen, only the columns of blood; the central white streak, especially conspicuous in the arteries, is due to the reflection of light from the cylindrical blood surfaces. In arteriosclerosis this streak is much accentuated and of a lighter hue. Medullary nerve sheaths usually stop at the disc; occaionally they penetrate the eyeball and appear as white, crushlike patches at its periphery. Rarely they may appear on the fundus, quite a distance from the disc. Latter appearance has been mistaken for albuminuric retinitis, especially if albumin was found in the urine. The following appearances are found in arteriosclerosis: Central white streak is accentuated; occasionally vessels appear as mere white streaks, no blood being seen (silver-wire arteries); sometimes the blood is visible in several segments of the artery only. Arteries are tortuous, though this appearance *per se* is not of pathological importance, unless accompanied by other changes. Veins are pressed upon when crossed by the arteries; vein appears dilated on distal and attenuated on proximal side of the artery. Aneurysmal dilatations of the arteries are very rare. Hemorrhages are flameshaped, if in the nerve layers and small. These leave small white patches when absorbed. Deep hemorrhages are globular or hemispherical. In the macular region such hemorrhage may cause immediate blindness, which may slowly give way to partial vision, blood being absorbed and nerve fibers not injured totally.
